35. *C. The Duration* of this general diffusive form of cynanche is very various. If the respiratory passages become early affected, or if the disease assumes a very severe form, a fatal result may occur in the course of two or three days from the commencement of the attack; but this seldom takes place before the 5th or 6th day; and occasionally it occurs at even a much later period, owing either to vital exhaustion, to contamination of the blood as stated above (§ 34), to lesion of the respiratory passages and organs, or to changes in the nervous centres and their membranes. Recovery generally occurs from the 7th to the 14th day, but sometimes much later. *Relapses, or repeated attacks*, of the disease may take place; the intervals between them varying with the circumstances or causes producing them; and the malady may even, from these and other causes, thus assume somewhat of a *remittent* or *intermittent* form, or even become *chronic*, recovery or a more acute attack supervening after an indefinite period.

36. *D. Terminations and Prognosis.*—*Recovery* often follows early and decided treatment; the inflammation of the throat presenting a less livid hue, the swelling subsiding, and deglutition becoming more easy. When these changes are attended by an improvement in the states of the pulse and skin, and in the several secretions and excretions, then this result may be expected with certainty. More unfavourable symptoms even than those already mentioned sometimes appear, and indicate irritation of the nervous centres, either by the contaminating operation of the miasms causing the disease, or by the interruption of the depurating functions; the blood in either case being affected, and vital power depressed. These symptoms are convulsions in children; delirium and restlessness in young persons and adults; followed by stupor, coma, pickings of the bed-clothes, &c. These generally follow rapidly upon the extension of the inflammation, or rather of the local morbid action to the œsophagus, to the larynx, and trachea, or to the Eustachian tubes and internal cavities of the ears. The severity of the local symptoms, the diffused swelling produced by the infiltration of the sub-mucous cellular tissue, as well as by capillary injection and congestion, and the viscid exudation from the diseased surface, increase all the symptoms connected with deglutition and respiration, and often threaten, and sometimes occasion, death by asphyxia, especially in children and young subjects, convulsions often also accompanying this event. The danger is generally great in proportion to the difficulty of respiration, to the dark hue and swelling of the throat, to the fetor of the breath, to the tumefaction of the sub-maxillary regions and neck, and to the weakness, smallness, and frequency of the pulse. Lividity of the face, lips, and tongue; a dirty, dark hue of the general surface, and blueness of the fingers and nails, are commonly fatal signs. Suppression of urine, and involuntary or unconscious intestinal evacuations, are also indications of impending

dissolution, especially when they are preceded or attended by the foregoing symptoms.

37. The dark colour of the throat, the sanious discharge from the mouth, and the gangrenous or fetid odour of the breath, have induced a belief, especially among some writers of the last century, that *gangrene* or sphacelation of one or more of the parts affected supervenes and occasions death. But actual sphacelation of any of these parts rarely occurs during the life of the patient; although the swelling, sanious or sero-sanious infiltration, and softening of the parts, are sometimes initiative of this alteration, and approach it more or less soon after dissolution. In the rare cases in which sphacelation of a portion of the inflamed surface takes place, a slough usually sufficiently apparent is formed, and, if the treatment be active and judicious, it is thrown off, leaving an ulcerated cavity or loss of substance more or less manifest according to the amount of the disease. In these cases, the danger may be less (recovery sometimes occurring) than when the morbid action is more diffused; the constitutional symptoms, or those connected with the nervous and vascular systems, and with the state of the blood and of the excretions, evincing by their severity a greater amount of risk than is denoted by the local sphacelation. This alteration, instead of constituting a distinct variety of cyananche, is merely an accident, or result seldom supervening, and is as likely to occur in one form of the disease as in another, although it is consequent upon the severity of the local affection, whether that affection be simple, or complicated with scarlatina or scurvy, or any other constitutional malady. The *phagedenic* or gangrenous stomatitis, affecting in rare instances infants and young children (see *art. STOMATITIS*, § 24, *et seq.*), sometimes extends to the fauces and throat, if it be not quickly arrested, and the poisonous action of mercurials, particularly in this class of subjects, and in adults who are susceptible of this action, is occasionally exerted in the throat and mouth in this destructive manner.

38. *E. The associations or complications of inflammatory affections of the throat*, in their partial or more general forms, are very numerous. They are commonly at first *symptomatic* manifestations of a more general or of a febrile nature; and they not unfrequently become most troublesome and even dangerous complications, not merely from their severity, but also from their extension, as shown above (§ 36), to one or more of the passages leading from the throat to other organs, and even to those organs themselves. In the exanthematous order of fevers, and sometimes also in the more simple continued fevers, these affections are often most serious complications. They are still more particularly so in scarlet fever, and sometimes in erysipelas of the head and face. They are often present in scurvy and other forms of cachexia; and they are frequently associated with the inflammatory states of dyspepsia, and in gastro-enteric disorders, both acute and chronic. In many organic maladies seated in the abdominal and respiratory organs, chronic affections of the throat, and sometimes also of the mouth and tongue, often supervene, especially at a far-advanced stage of these organic maladies, and indicate depressed organic nervous power, and change of the circulating fluids; thus evincing an unfavourable and generally a fatal issue. The affections of the throat and

mouth, in the advanced course of these maladies, especially of tubercular diseases of the lungs, often assume an apthous appearance, and increase the distress of the patient.

[M. BILLARD (*A Treatise on the Diseases of Infants*, translated by JAMES STEWART) has called attention to the fact that the veil of the palate and the isthmus of the fauces, in young children, are generally red and injected, and that the whole pharynx is in a high state of congestion, its degree being in proportion to nearness to birth. In 200 children, aged from one to ten days, that had died from various diseases, he found the isthmus of the fauces injected in 190—the injection being generally uniform, but sometimes in the form of ramifications. The tonsils also partake of this congestion, showing the intimate connexion between the vascular system of the skin and that of the mucous membrane of the mouth, throat, and probably the whole intestinal canal.

Though it be sometimes difficult to recognise inflammation of these parts in young infants, for the reason just stated, yet it may be safely inferred, when the redness continues beyond the ordinary time of the disappearance of the congestion in young infants, viz., ten or twelve days; or when it occupies several points, instead of being spread uniformly over every part of the throat; or, lastly, when some of the other symptoms of cyananche exist at the same time with the redness, and it occurs at a time when the parts are not naturally congested.

If either this or the following form of inflammation occurs in infants, unless it be very slight, there will be difficult deglutition, regurgitations, or vomiting, with an expression of pain on attempting to swallow; tumefaction of the tonsils, with pain and tenderness of the neck on pressure, and an alteration of the cry and the physiognomy.

Inflammatory affections of the throat and fauces derive much of their importance from the fact that the same affections of the air-passages have their origin generally in the former, the inflammation extending by continuity to the respiratory tubes.

In disease, the mucous membrane lining the throat and air-passages becomes changed from the pale rose colour of health to a dark scarlet, purple, or violet colour, according to the form and insensibility of the inflammation; if acute, the red or violet colour is nearly equally diffused over the whole surface, while in the chronic forms it appears in irregular circumscribed patches, presenting highly coloured centres, which become paler towards their circumference. In some cases we find the membrane lining the throat and fauces swollen and of a bright red colour, pouring out mucus or pus upon its surface. In another, the membrane appears tense and much injected, and, instead of pouring out a mucous secretion, is dry and glossy. In a third form, the investing membrane is pale, relaxed, and cedematous, while serous infiltrations distend the sub-mucous cellular tissue. In another, there is plastic exudation, forming a dense adventitious membrane, as above described by our author. In most of these latter cases, there will be observed at a very early period white or ash-coloured patches of albuminous exudation spread over the fauces and pharynx, while the membrane not covered by them is of a deep scarlet or Modena red colour. They are not unfrequently mistaken for

superficial sloughs, and, when cautiously removed, the membrane will be found divested of its epithelial coat. • M. BRETONNEAU has recorded several cases where this false membrane extended down to the cardiac orifice of the stomach; while in other instances it lined the trachea and larger bronchial tubes.

There is still another form of disease of the throat, unnoticed by our author, which may be characterized as *follicular disease of the pharyngeal mucous membrane*, or *Follicular Pharyngitis*. This is *one*, and only *one*, of the forms of the disease which has been called *clergyman's sore throat*, to which we first called attention in an article entitled "An Enquiry into some of the Causes of Disease among the Clergy," and published in the "*Lit. and Theol. Review*," Sept., 1836. This affection has doubtless always prevailed to a greater or less extent, although from some unknown causes it has been far more prevalent since about the year 1830, when this country was visited by the influenza in an epidemic form. At first it appeared to be confined chiefly to public speakers, especially the clergy; but probably this was only apparent, inasmuch as this class would be more likely to apply for medical relief, in consequence of the inconvenience it occasioned in the discharge of their duties. Particular attention has been called to this disease of late, in consequence of its very general prevalence. Dr. HORACE GREEN has described it under the name of *follicular disease of the pharyngo-laryngeal membrane*, and *tubercular sore throat*, while Dr. POKEN has named it *Tubercles of the Larynx and Fauces*.

This disease consists essentially in inflammation of the mucous follicles, generally sub-acute, and terminating in hypertrophy, ulceration, or induration of these glandulæ, or infiltration of tuberculous matter into their substance. Whatever parts may be involved in the disease, it nearly always commences in the fauces and pharynx. *Follicular pharyngitis* is usually very insidious in its approach, and may exist for some time without causing particular inconvenience; at length, however, the voice grows husky, there is an uneasy sensation in the throat accompanied with frequent hawking and inclination to swallow, while there is a very copious secretion of viscid, opaque mucus poured out by the diseased follicles. There is rarely any cough, although there is more or less soreness about the region of the larynx. If we examine the throat at this stage of the disease, we shall find the mucous follicles hypertrophied, and the membrane injected, while the epithelial coat will have been more or less destroyed. If the disease have long existed, the follicles may be greatly enlarged, indurated, or filled with a yellowish substance resembling tubercular matter, while the membrane will be extensively covered with a layer of muco-purulent secretion. The disease may extend down the larynx, invading the vocal cords, when the voice becomes weak, hoarse, or husky, and may be wholly lost, or speaking is followed by a sensation of pain and soreness in the larynx, and there is more or less general as well as local debility. The absence of cough is a characteristic feature of this form of disease.]

39. V. TREATMENT.—i. OF TONSILLITIS.—The treatment of tonsillitis is nearly the same as that of other forms of angina.—A. At the commencement of the complaint *acidulous* and *demulcent*,

or *emollient fluids*, may be used; and the open mouth may be frequently held over a basin containing about half a scruple or scruple of camphor and an ounce of vinegar, on which about a pint of boiling water is poured, the patient directing the *fumes* from these towards the throat by placing half a sheet of paper before and above his open mouth, and under his nostrils, so as to allow respiration to be free. If the *vapour* from these excite cough (which it will not occasion if the paper be adjusted over the upper lip, so as not to allow the fumes to be respired by the nostrils) either the quantity of water may be increased, or that of the other ingredients diminished. A sufficiently active aperient and alterative pill ought to be given at bed-time, and a *purgative draught* in the morning; and the feet and legs should be plunged in warm water, containing salt and mustard, the *pediluvium* being repeated according to circumstances. In mild cases, or in delicate persons, these means, aided by *diaphoretics*, and by *embrocations* to the throat and neck, will generally be sufficient to remove the complaint; but in strong, robust, and sanguine habits of body, or when the febrile action is considerable, is sthenic or phlogistic, *venesection*, or *leeches* applied behind the ears, or both modes of depletion may be practised.\* In large towns, and in persons living in low, close localities, and in the insufficiently nourished, *blood-letting* is as often injurious as beneficial. For males, *cupping* on the nape of the neck—the quantity of blood taken by it having due reference to the state of the patient—should be preferred; but for females, neither this mode of depletion, nor the application of leeches to the neck, is eligible, on account of the marks which are left by them. For these latter, therefore, *bleeding* from the feet while they are plunged in warm water, or the application of a few leeches below the groins, especially if the catamenia be delayed, suppressed, or difficult, or scanty, should be preferred. I have never seen much benefit derived from the application of leeches to the neck in tonsillitis; and the recommendation of some writers to apply them to the inflamed tonsils is generally repugnant to the patient, and is seldom advantageous.

40. B. *Fomentations* and *poultices*, of an irritant nature by some, and of an emollient kind by others, have been advised; either of these may be of service, and either of these may be quite useless.† I have generally prescribed *terebinthinate epithems* and *embrocations* to be applied around the neck, two or three folds of flannel being moistened by the substances prescribed, and covered by a napkin or handkerchief. These substances, conjoined with the turpentine, have been varied according to the features of the case, as directed in various parts of this work, and in the APPENDIX (see *Form. 311*); and are beneficial in all the forms of angina. They may be so prescribed as

\* [We have found large doses of *Dover's Powder*, aided by a dilute warm solution of the *nitrate*, or *acetate of potash*, freely taken, very successful in arresting this disease. If inflammatory action runs high, a little *antimony* should be added. Free purging is indispensable, carefully avoiding all mercurials. If necessary, we apply leeches under the jaws and cups behind the ears. In many cases the treatment must be very active to prevent the formation of an abscess.—*Ed.*]

† [Dr. WATSON says, "The only gargle which is admissible, in the commencement of the malady, is one of warm milk and water." Dr. SOUTH recommends the steam of hot water, taken through an inhaler.—*Ed.*]

to produce erubescence of the external surface, or as not to occasion this effect, according to the intention of the physician. In addition to the use of laxatives and aperients, or purgatives, and of diaphoretics, it has been usual to prescribe *gargles* to the throat. I have seldom seen them of much service. But refrigerant and emollient fluids, in the severe and *sthenically* inflammatory cases, as the nitrate of potass, solution of the acetate of ammonia or muriate of ammonia and mucilage, in camphor mixture, may be taken frequently, and held in the throat for some time, while the head is thrown back, before they are swallowed, or before they are thrown out.

41. C. The more *asthenic forms* of tonsillitis occurring in weak, ill-fed, or cachectic persons, or in those weakened by a foul atmosphere, or by previous disease, ought not to be treated by local or by general blood-letting. After the excretions and fecal accumulations have been duly evacuated, organic nervous power and the depurating functions should be promoted by suitable means; and the local extension of the morbid action ought to be prevented by the applications which have been found most successful in attaining these ends. The action of the excreting organs should be increased by conjoining *tonics* with *aperients*, and these with the *alkaline carbonates*. These medicines may be taken at night or early in the morning, or at both periods; while the decoction of *cinchona*, with the compound tincture of cinchona and the solution of *acetate of ammonia*, may be given during the day. In many cases, the dilute *hydrochloric acid*, or the nitro-hydrochloric acids, or the pyroligneous acids, may be substituted for the acetate of ammonia; and each dose of such mixture may be held for some time in the throat, as just advised, before it is swallowed; or the same mixture may be used very frequently as a *wash* for the throat while the head is thrown back, and be afterward ejected. I have in these cases also prescribed the sulphate of quina with compound infusion of roses, dilute sulphuric acid, &c.; but I have had reason for preferring the medicines now advised, to this last. In the more *asthenic*—in the gangrenous, putro-dynamic, or malignant, as they have been termed—still more *astringent* and *antiseptic gargles* or *washes* for the throat may be prescribed, especially those with *krameria*, *capsicum*, sulphate of zinc, &c.; or those with the chlorides, or with chlorinated water or solutions; or others with decoctions of bark and pyroligneous acid or creasote. I have used with much advantage in those cases gargles and washes with strong *tar water*; and when this last is not too strong to swallow, then a portion of it will generally be taken into the stomach with manifest benefit. In these cases, also, the *fumes* arising from hot water poured over camphor, with myrrh, vinegar, or pyroligneous acid, and a little creasote, may be inhaled or passed into the throat, as directed above (§ 39), or the weak fumes of tar may be similarly used—or the vapour of hot water poured on tar.

[In this form of the disease, a strong solution of nitrate of silver (40 grs. to the ℥j.) will often prove useful, and there is reason to believe that in the first form an early application of the same would probably arrest its progress.]

42. Several other measures, besides those now mentioned, have been prescribed for tonsillitis. Dr. MONGE has advised the tonsils to be *scarified*; and in the more chronic and indurated states of

the disease this may be of service. M. RANQUE prescribed the *pyroligneous acid* to the inflamed tonsils; M. LAENNEC, of Nantes, the insufflation of *powdered alum*; M. BENNATI, *gargles*, with a strong solution of alum; and M. GUYTON-MORVEAU, powdered *carbonate of lime*. These, as well as other applications about to be noticed, are more beneficial in the chronic enlargement of the tonsils than in the acute or early inflammations of those organs. *Gargles* of various kinds have been advised by numerous writers since the days of HIPPOCRATES and of AVICENNA—cooling and emollient gargles in the more *sthenic* or *phlogistic* cases; warm, stimulating, and antiseptic gargles in the *asthenic* or *malignant*; and astringent gargles when the disease is attended by relaxation. *Dry-cupping* on the neck has been recommended by HIPPOCRATES, ARÆTEUS, PAULUS ÆGINETUS, KORTUM, and others; but to be useful it should be often repeated. *Emetics* were much used by the older writers in all inflammatory affections of the throat. They are most beneficial when such affections are complicated with torpor of the liver, or with biliary accumulations in the gall-bladder and ducts. When exhibited after the formation of matter in the tonsils, they generally occasion rupture of the abscess and immediate relief. *Blood-letting* has been very generally employed for the *sthenic forms* of guttural disease. HIPPOCRATES, CELSUS, ARÆTEUS, CÆLIUS AURELIANUS, ALEXANDER TRALLIANUS, AVICENNA, and many writers of the 16th and 17th centuries, advised the blood to be drawn from the sublingual veins; but the practice has fallen into so complete disuse, that no one at the present day is able to give an opinion as to its merits. Bleeding from the feet was likewise advised by many writers, but not so generally as bleeding from the nasal veins.

[We have frequently resorted to free scarification of the tonsils, in acute inflammation of the glands, with the best effects, and have seen no case made worse by this treatment. The scarifications should be shallow, and may be made with a palate-lancet, or a common bistoury, the edge of which is guarded nearly to the point. This operation, however, is not unattended with danger. WATSON mentions one case of fatal bleeding from a wound of the internal carotid, and another where very serious hæmorrhage occurred from this simple operation. LAWRENCE mentions a similar case from premature puncturing of the tonsil, to evacuate matter. Sir B. BRODIE relates two cases, where death from bleeding ensued from puncturing a tonsillar abscess. PORTAL, ALLAN BURNS, and TYRRELL, all mention similar cases. The incision or puncture, in these cases, should be made directly backward, or from without, inward and backward, to avoid puncturing the internal carotid artery. Accidents of this kind, however, are extremely rare, and will never happen if the above directions be followed. In most cases of tonsillar abscess, the effort of vomiting, excited by emetics, is sufficient to burst the walls and discharge the pus; but this is attended with so much suffering, that it is far better to open the abscess. After the matter has been discharged, soothing gargles, with honey, should be frequently used, and commonly they produce a speedy cure. Astringent gargles are best suited to cases where the swelling still continues, although the inflammation has subsided. The internal use of powdered *guaiac*, in doses of ʒss. ev-

ery six hours, has been recommended as a specific in the cure of tonsillitis.]

43. *D.* When the disease has passed on to suppuration or to *abscess of the tonsils* (§ 8, *et seq.*), as it generally does if the above means fail to arrest it in a few days, then the distention attending this state almost threatens suffocation, and the cough, difficulty of breathing, or the occurrence of retchings, &c., tend to rupture the abscess, and relief is obtained. But before the distressing symptoms occur, and as soon as fluctuation is felt on applying the finger, an incision should be made for the escape of the contents. Frequently the abscess bursts before the symptoms become urgent, and the disorder soon subsides. If this should not be the case, the local and constitutional means already advised should be persevered in; and, if a chronic remittent or intermittent state of the disease follow, the means about to be noticed will generally succeed in restoring the parts to a healthy condition.

44. *ii.* THE TREATMENT OF PELLICULAR OR PLASTIC INFLAMMATION OF THE THROAT has been the subject of much discussion both in this country and on the continent.—*a.* *Blood-letting*, general or local, or both, should be early employed, when the habit of body, age, and strength of the patient, and the sthenic character of the local affection and of the attending fever, indicate the propriety of the practice. But I have never seen much advantage obtained from too copious or too frequently repeated depletions in this malady. It should be recollected that the disease occurs chiefly in an epidemic form, and epidemics seldom require large depletions, even although vascular action may appear greatly excited. In these maladies the excitement greatly exceeds the amount of vital power. *Emetics* are more generally appropriate, and when blood-letting is proper, they should soon follow this measure, the terebinthinate *embrocations* already mentioned (§ 40) being applied around the neck and throat. *Purgatives* are of use, but of much less use than in the other forms of guttural inflammation. The bowels, however, should be kept in an open state throughout the disease by medicines taken by the mouth or administered in enemata, and all the depurating functions ought to be promoted.

45. *b.* The *local treatment* of plastic angina is of the greatest importance, and especially for the severe and rapidly spreading cases. For these the dilute *hydro-chloric* or *nitric acids*—the dilution being less in the most severe, and proportionably greater in the milder cases—should be applied by means of a piece of sponge firmly tied on the end of a piece of whalebone. Either of these acids, or a strong solution of the *nitrate of silver*\* [or *creasote*,] ought to be thus applied over

and around the parts covered by the pellicular exudation, and the application repeated according to its effects and the urgency of the case. It should be carried sufficiently down into the pharynx, and over the base of the tongue and epiglottis, to prevent the extension of the exudation to the larynx.\* In the milder cases, the *chloride of mercury*, or the *biborate of soda*, mixed in fresh butter or in honey, in the proportion of from one to two drachms of the former to an ounce of the latter, will prove quite as efficacious as the mineral acid or the nitrate. Having arrested the disease by these means, or having so employed them as to change the morbid action in the affected parts and to prevent its extension, the treatment about to be recommended for the next variety—the simple and complicated forms of diffused *cynanche*—may be pursued, appropriately to the features of individual cases. In most instances, the *fumigations* and *embrocations* advised above (§ 39, 40) will be sufficient to restore the local affection to health, when aided by the means requisite to promote the secretions and excretions, to allay febrile action when it is materially excited, and to support vital power when it is deficient. For these purposes the measures already mentioned and those about to be noticed are quite appropriate. MM. BRITONNEAU and GILLON at first advised the *insufflation* of a powder into the throat consisting of either the dried sulphate of alumina or chloride of mercury, mixed with powdered gum acacia; but it was found that the frequent passage of a portion of the powder into the larynx and trachea often occasioned unpleasant and even dangerous effects. The acids or the nitrate just mentioned—the former slightly diluted, the latter in strong solution, in the more severe epidemic cases—were therefore preferred by them and by others in this form of *cynanche*.

[Powdered *alum*, made into a paste with water and honey, and applied to the throat by means of a camel's-hair pencil or sponge probang, is often very beneficial. Great advantage will often arise from the use of a gargle made of salt, vinegar, and capsicum. A solution of chloride of soda or lime has been found useful. If the disease, however, be constitutional, little dependence can be placed on local measures only.]

46. *iii.* TREATMENT OF DIFFUSED CYNANCHE, SIMPLE AND COMPLICATED.—*A.* This form of the disease is so frequently dependent upon disorder of the stomach, or of the biliary functions, or of the bowels, or of all these, that it is very often necessary to commence the treatment with an *ipæacuanha emetic*, promoting its action by drinking a warm infusion of chamomile flowers. *Blood-letting*, in this state of the disease, is seldom required, unless in persons of a gross, plethoric habit of body, when it may be advantageously employed, the quantity and mode of depletion being adapted to the peculiarities of the case. After the operation of the emetic, a full dose of calomel should be given, either alone, or conjoined with other *purgatives* and aromatics or spices, or with camphor, and according to the character of the febrile symptoms, and be followed in a few

\* [In the application of the *nitrate of silver* in the follicular and other forms of pharyngeal inflammation, a solution of the crystals should be employed, the strength varying, according to the kind and degree of the inflammation, from one to four drachms to the ounce of distilled water. Where the follicles are enlarged and the disease has become chronic, the solution should be applied by the probang and sponge, at first every other day, for two or three weeks, afterward about twice a week, till the granular and vascular mucous surface assumes a healthy appearance. Where the diseased follicles are confluent, presenting a tuberculated form, they should be touched occasionally with the solid nitrate. Sometimes the mucous crypte in the posterior nares become diseased, causing a morbid and offensive secretion, which, falling down, keeps up an irritation in the posterior fauces. In such cases the disease may be reached by the curved syringe, using a solution of the nitrate of silver, of the same strength as before; or a piece of whalebone, bent to a right angle at a

distance of one inch and a half from the end, and armed with a small piece of soft sponge, may be carried back of the velum, so as to come in contact with the affected parts. The syringe, however, is the most effectual. If the *uvula* be permanently hypertrophied, both thickened and elongated, excision will be advisable.]

\* [In order to bring the pharynx fully into view, the spatula, bent to a right angle, should be employed.—*Ed.*]

hours by a stomachic purgative draught, and by a cathartic enema, if the operation on the bowels be insufficient. The *terebinthinate embrocations* and the *fumigations* mentioned above (§ 39, 40) should not be omitted, and the febrile or general disturbance ought to be treated conformably with the character which it may assume. In most cases I have found that, after the due operation of the above means, the decoction of cinchona, liquor ammoniæ acetatis, the sesqui-carbonate of ammonia, and compound tincture of cinchona, or the decoction with hydrochloric acid, &c., have soon removed all disorder. In most cases the *washes* and *gargles* of the throat already advised have also been of use.

47. *B. The Guttural Inflammations* which occur as *complications* of either local, general, or specific diseases, are of an asthenic or diffusive nature, and usually require the *tonic or restorative*, conjoined with the *alterative*, means already recommended. At the same time, the treatment appropriate to these ought to be enforced; and most commonly the measures which are the best suited to the primary disease are most beneficial for the guttural affection. In these complications, the *fumigations* of the throat, with stimulant and antiseptic substances, and *washes* or *gargles*, with similar or with astringent medicines (see § 41, 42), and *embrocations* applied externally as advised above (§ 40), are generally indicated and beneficial. The functions of the skin, kidneys, and bowels, ought to be duly promoted by conjoining such depurating medicines as the states of these functions may require, with tonics and alteratives; the best alteratives being those which depurate the blood, and at the same time neutralize or remove, or counteract morbid materials or elements which may accumulate in the blood, either previously to, or in the course of, developed forms of disease. Of these sufficient notice has been taken above, and in the article on the principles of THERAPEUTICS.

48. *C. The Diet and Regimen* for inflammatory affections of the throat differ very much in different cases. In the more *asthenically* inflammatory the regimen should be strictly antiphlogistic, and the drinks or beverages allowed ought to be refrigerant, demulcent, or emollient, either of these properties predominating according to the states of the skin and urine. When the guttural affection is *asthenic* or diffusive, the beverages or drinks may be more restorative; and when the affection is severe or malignant, or is attended by an offensive or putrid odour of the breath, then *vinum*, more or less diluted, may be given in the intervals between the exhibition of the *tonic and antiseptic medicines* mentioned above. The *diet and regimen*—or, rather, a successful adaptation of both to the intimate nature of the case—must be directed mainly by a correct interpretation of the states of the pulse and of the circulating fluids; and this interpretation can be attained only after close observation, profound thought, and diversified as well as extensive experience. The physician, thus enlightened, will adapt the means to the end, and will direct such diet and regimen as will be congruous not only with the state of the patient, but also with the internal and external remedies which are prescribed. Of the regimen, the most important part is the removal of the patient, from the operation of such miasms or exhalations as may have either caused or aggravated the complaint, to a pure or temperate and

dry air. In all cases, also, however slight, moderation in the use of animal food, or even a temporary abstention from this food, as well as from malt or other fermented liquors, should be enforced, unless when wine or other beverages or drinks of a restorative kind are allowed medicinally. Wine ought to be restricted chiefly to the asthenic, diffusive, and complicated cases of the malady. During *convalescence*, the diet should be abstemious, and chiefly farinaceous. As strength is obtained, particularly after the more severe and complicated attacks, the food should be generous but digestible; and change of air, tonics, and tonic and alterative mineral waters, ought to be prescribed. Travelling, voyaging, and exercise in the open air, will also prove extremely beneficial.

#### 49. VI. STRUCTURAL CHANGES OF THE THROAT AND TONSILS.

CLASSIF.—IV. CLASS, I. ORDER (*Author in Preface*).

*Structural Lesions* of the Throat and Tonsils are generally produced, 1st, by inflammation; 2d, by the syphilitic infection; 3d, by mercurial action; 4th, by the scrofulous diathesis and tubercular disease; 5th, by prolonged disorder of the digestive organs; and, 6th, by mechanical injury. These lesions may be confined to the tonsils, or to the pharynx, or to two or more of the parts forming the fauces and throat. Certain of them are noticed under the heads PALATE and UVULA, LARYNX, &c., and others are comprised under VENEREAL DISEASES, the *Mercurial Poisons*, and SCROFULA, owing to their being very important manifestations of these constitutional afflictions. In the brief view which will be here taken of structural lesions of the throat and tonsils, attention will be chiefly directed to those which are produced by inflammation, by disorders of the digestive organs, and by a cachectic or morbid diathesis, the exact nature and causes of which are often imperfectly ascertained. The *syphilitic* and *mercurial* sources of lesions of the throat are fully considered under the heads just referred to.

50. Organic lesions of the throat are most frequently the consequences of some form of inflammation—sthenic or asthenic, common or specific—the character, severity, or the duration of which is productive of alterations in the structure of one or more of the parts in which the inflammatory action has been chiefly manifested. These consequences are, suppuration or abscess; ulceration; œdema, or serous or sanious infiltration; ecchymosis; varicose state of the venous capillaries and congestion of vessels; exudations on the mucous surface of either an aphthous, pulpy, or membranous nature, with or without superficial ulceration or excretion; softening, tumefaction, pulpy degeneration and discoloration of the mucous and sub-mucous tissues; vesicular and pustular formations and ulcerations; phagedenic ulceration; sloughy or gangrenous disorganization, or sphacelation. These changes take place independently of either the *syphilitic infection* or the *mercurial poison*; although, in addition to the forms of ulceration and other structural changes peculiar to these poisons, certain of the alterations now enumerated sometimes acknowledge the same origin.

51. I. STRUCTURAL LESIONS OF THE TONSILS AND FAUCES have been partly considered above (§ 10, 24, *et seq.*). Superficial ulceration, relaxation of the fauces, elongation and œdema of the uvula, tumefaction and induration of the tonsils,

congestion or hyperæmia of the guttural surface, extending to the Eustachian tubes and to the glottis and rima glottidis, and increased mucous discharges from the affected surfaces, are the most frequent and the least serious changes which these parts undergo, and are generally the consequences of catarrhal inflammation, or of those less dangerous states of inflammation which depend upon disorders of the digestive organs, or which complicate exanthematous fevers, especially when the former of these become chronic, or frequently recur.—*A. Abscess* or suppuration has been already noticed (§ 8) as a frequent consequence of tonsillitis. It may also, although rarely, appear in the velum palati or the upper part of the fauces. *Edema* and *serous* or *sanious infiltration*, ecchymosis, and softening of the fauces and tonsils, are most commonly the effect of the more asthenic or adynamic states of inflammation, as remarked in the guttural inflammations attending scarlatina, erysipelas, &c., or are consequent upon stomatitis, especially when occasioned by the mercurial poison. In these circumstances, the affected surface may be covered by grayish, shaggy or pulpy, dirty or sanious exudations. The plastic exudation which characterizes the pellicular form of cynanche (§ 21, *et seq.*), and the changes consequent upon affections of the throat in scarlet fever, are described under their respective heads.

52. *B. Vesicular and pustular formations* are rarely seen, and only in the severer forms of small-pox. In these cases the mucous tissue is softened, tumefied, and often covered by a plastic mucous secretion. *Excoriations* and *exfoliations* of portions of the epithelium of the fauces occur in the course of many of the affections of the throat, and are often connected with the several states of exudation noticed at this and other places. *Ulceration* of the tonsils and fauces sometimes follows the detachment of these exudations, but not so frequently as is commonly supposed; nor is phagedenic ulceration, or superficial sphacelation often seen, unless after the poisonous action of mercury, and in the complicated and malignant states of cynanche, as already shown (§ 36–38). The rapidly-destructive ulceration which characterizes *noma* or phagedenic stomatitis sometimes extends from the gums and cheeks to the fauces. The more chronic forms of ulceration are chiefly consequences of scrofula, syphilis, and mercurial action, and are noticed in other places.

53. *C.* In addition to *enlargement* and *induration* of the *TONSILS*, these bodies may contain, in their lacunæ or in their structure, substances varying in appearance and hardness from that of tubercle, to that of indurated calcareous formations—or small calculi. They consist of concentric layers in some instances, and of agglomerated grains in others; are of a yellowish white or grayish hue; the more soft and friable resembling tubercular matter; the harder containing phosphate and carbonate of lime. They vary in size from that of a millet-seed to that of a pea, and are often spontaneously detached from the tonsil. They are probably the more permanent or saline remains of small collections of pus, or of small chronic abscesses in the tonsils. Some of these contain, with the ingredients just named, a little fatty matter and a coagulated albumen. *Cysts* and *acephalocysts* are very rarely seen in the tonsils; and *cancer*, in its several forms, is as

rarely found primarily in the tonsils, although it not unfrequently attacks parts in the immediate vicinity, and then often involves these organs. The tonsils and portions of the fauces may be destroyed by the ulceration produced by phagedenic stomatitis, or by syphilis, or by mercurial action, and be followed by cicatrization—the *cicatrices* ultimately contracting so remarkably the aperture of the fauces as not to allow the passage of the more solid kinds of food; but these occurrences are very rare. Fibrous *polypi* sometimes occur in the fauces, but much less frequently than in the posterior nares; and vary in form, as well as in firmness or softness. Their investing mucous membrane is generally spongy, is often ulcerated and disposed to bleed.

54. ii. ORGANIC LESIONS OF THE PHARYNX.—These consist chiefly of *alterations of calibre*, of the changes consequent upon inflammation—especially *exudation*, *softening*, *abscess*, and *ulceration*—and of *fibrous* and *malignant formations*.—(a) *Dilatations* of the pharynx may be general as respects the parietes of the tube, and extend to the upper portion of the œsophagus, the parts thus presenting a *funnel-like shape*; or they may be partial, one side or part of the pharynx having become so much dilated as to form a *pouch* attached to the pharynx. In this latter case the muscular fibres are stretched, ruptured, or wasted, so that the pouch consists chiefly of mucous and cellular tissues; but these tissues may have been pushed out between the muscular fibres, thus forming, in the first instance, a *diverticulum* from the pharynx that has ultimately become dilated into a pouch. The funnel-like dilatations are often the consequence of constrictions of some kind in the œsophagus. *Constriction* of the pharynx is generally a consequence of malignant disease, or of tumours pressing upon the pharynx and upper portions of the œsophagus, or of the cicatrization following ulceration.

55. (b) *Inflammatory changes* are most frequently seen in the pharynx. These consist chiefly of *croupy* or *plastic exudations*, as described above (§ 20) and in the *art. CROUP*; of *aphthous exudations* in cases of thrush; and of *pustular formations* in very rare instances, in variola or after tartar emetic has been given in excessive doses. *Exudations of blood* from the throat sometimes occur during catarrhal or other inflammation of the pharynx or fauces, especially when these are attended by much irritation of the glottis and severe cough. The blood generally is seen in streaks in the viscid mucous expectoration. When the lower portion of the pharynx is affected, and when there are retchings as well as cough, the discharge of blood is occasionally more considerable; and it is then difficult to determine whether it proceed from the pharynx, or the œsophagus, or the stomach, or even from the bronchi or lungs; and whether it is merely an inflammatory exudation or a consequence of ulceration. These points can be determined only by the history of the case, by a careful examination of the sputa, and by a due consideration of all the phenomena. *Softening* of the internal coats of the pharynx, and especially of the mucous and sub-mucous tissues, is seen in typhoid, exanthematous, and malignant fevers, and in scurvy and after the ingestion of caustic, alkaline or septic, or other poisons. *Abscess* or suppuration of the pharynx has been already noticed when treating of inflammation (§ 18). It may give rise to ul-

eration, and to still more extensive and dangerous alterations of parts in the vicinity, as shown above; but *ulceration* is much more frequently produced by syphilitic infection (*see* *VENEREAL DISEASES*). Ulceration generally takes place in the posterior portion of the pharynx, although it has, in rare instances, attacked the anterior or latter portions, and extended into the larynx or trachea.

56. (c) *Fibrous tumours* or *polypi* have been found in the pharynx, or implicating the upper region of it and the posterior nares; but they very rarely arise primarily from this portion of the alimentary tube. *Cancerous* or *carcinomatous* or *medullary formations* sometimes affect this part, but not so frequently as the œsophagus. In the cases of carcinoma of the pharynx which I have seen, the base of the tongue and the pillars of the fauces became implicated, and the canal or passage into the œsophagus narrowed, and ultimately so remarkably reduced as to render the conveyance of nourishment into the stomach most difficult or nearly impossible. The carcinomatous ulceration has in some instances been followed by fatal hæmorrhage before this change has supervened.

57. (d) *Foreign bodies* of various kinds, and especially the bones of fish or of other animals, may be fixed in the pharynx, or penetrate, partially or altogether, the parietes of the canal, and give rise to inflammation, abscess, &c. Foreign bodies of every possible kind may be swallowed or be attempted to be swallowed, and produce either immediate or more or less remote effects of a serious or dangerous nature, for which surgical as well as medical aid may be required—the former immediately, the latter subsequently. Of wounds of the pharynx it is not my province to speak.

58. iii. *Treatment of Organic lesions of the Throat.*—a. *Enlargement and Induration* of the tonsils are generally the consequences of neglect of the slighter forms of tonsillitis, of repeated returns of the disease, or of the chronic remitting forms already mentioned (§ 9, 10), especially when occurring in the scrofulous diathesis, and in delicate persons. For these states of disease numerous methods of cure have been employed. The scarifications and local means already noticed (§ 39, *et seq.*) may be first tried; and if these fail, the measures about to be advised may be employed, and modified according to circumstances, while the general health should be promoted by change of air, and by a suitable diet. But, with the promotion of health and strength, the several depurating functions must be regulated and severally increased. Tonic infusions or decoctions with hydrochloric or nitro-hydrochloric acid, or with pyroligneous acid, or, instead of acids, the alkalies and the iodide of potassium, or the chlorate of potass, may be severally prescribed. The local application, by means of a hair brush, of a weak tincture of iodine, or of a strong solution of the nitrate of silver, or of dilute nitric, or hydrochloric, or pyroligneous acid, has often been found of the greatest service, especially while the iodine ointment or terebinthinate embrocations have been applied externally.

59. b. *The removal* of enlarged and indurated tonsils has been advised since the days of CÆLUS down to the present time. Some surgeons have employed ligatures to the enlarged tonsil, others have had recourse to excision. Unless the enlargement have resisted scarifications and the

means already recommended, after a sufficient trial has been given, and unless the enlargement greatly impedes the voice, speech, and deglutition, I would not advise either of these operations to be performed; for, knowing that the functions of the tonsils are to secrete a lubricating fluid, for the superior orifice of the glottis, and for the epiglottis and pharynx, it necessarily follows that the extirpation of these organs deprives these parts of what is essentially requisite to the healthy discharge of their offices. Hence the throat becomes unpleasantly dry and husky. Voice and speech are thereby remarkably injured, and are incapable of being exerted for any considerable time. These effects I have observed to follow in numerous cases where the officious interference of surgeons has removed these organs. I have not known an instance of a female who had had a good voice who did not entirely lose it after the extirpation of the tonsils; and a similar result has often followed the excision of the uvula close to the velum palati.\*

[Where the tonsils are permanently enlarged and indurated, we have uniformly found local applications unsuccessful in reducing their size, and have resorted to excision as the only certain remedy. We have not often found it necessary to remove the entire gland; nor, when this only is done, is there any reason to fear that change in the voice, speech, and deglutition referred to by our author. In regard to the effects of the entire removal of the uvula, Mr. YEARSLEY states that the utmost pains have been taken to ascertain the results of the loss of the uvula, but in no one case can he find that the slightest inconvenience has arisen from its removal. Dr. H. GREEN also remarks, "In a large number of cases where I have found it necessary to amputate the uvula, I have not been made aware, in any instance, of the occurrence of inconvenience, either from its partial or entire removal. Ordinarily, however, I have not considered it advisable, in the operation, to

\* [Dr. F. H. Hamilton, of Buffalo, has published a history of fifty-two cases of enlarged tonsils, which he has extirpated (*Buff. Med. Jour.*, vol. iii., p. 189). In all the cases the glands were simply enlarged and slightly indurated, except in six or eight instances, where a few small tubercular deposits were found in them. Dr. H. has never seen them scirrhous or affected with any other malignant disease. In ten the enlargement was attributed to scarlatina, in seven to whooping-cough, in three to croup, and in eighteen to hereditary predisposition. Many of the patients had a scrofulous look, and some had enlargement of the cervical glands. The tonsillar enlargement was generally noticed between the fourth and seventh year of life. When left to themselves, Dr. H. thinks, enlarged tonsils will usually disappear before the twentieth year; but, as they predispose to tonsillitis, bronchial diseases, and croup, impair the general health, speech, and hearing, and cause dulness of intellect and petulance of feelings, &c., he advises their removal by excision. He has seen little benefit from other local means or general treatment. Excision should not be performed, however, when the tonsils are inflamed, unless the patient is threatened with suffocation, nor if the patient has a hæmorrhagic diathesis, nor if no other reason can be assigned than that they are enlarged. The operation may be performed at almost any age. Three operations were made on children two years of age. To check the bleeding a gargle of cold water will usually suffice, and if this does not succeed, apply snow or pounded ice or cold wet cloths about the neck, and especially opposite the seat of the tonsil. Dr. H. recommends the removal of the entire gland, as less likely to be followed by copious hæmorrhage. If one half only is removed, the enlargement, he thinks, is apt to go on. Neither the speech nor hearing is apt to be improved until after the lapse of months after the operation is made. Dr. H. has never known the speech or voice to be injuriously affected by the removal of the tonsils or uvula, nor any other inconvenience result from the operation.—*Loc. cit.*]

practice total excision, but have generally found it necessary, and quite sufficient, to remove the greater part of this organ."—*A Treatise on Diseases of the Air Passages, &c.*, New York, 1846, p. 209. This writer also states that he has not met with a single case where any serious inconvenience resulted from the subsequent hæmorrhage. One such case, however, was communicated to us recently by Prof. T. CHILDS, of Pittsfield, Massachusetts, where death was the consequence. Sir ASTLEY COOPER advises to remove only so much of the uvula as to reduce it to its proper proportions, believing that if the whole were removed, fluids could not be taken without their passing into the nostrils, and the articulation would be injured. Dr. SOUTH remarks that he does not advise it, because he knows it to be unnecessary; that "it is commonly sympathetic with irritations of the alimentary canal, and when that is quieted, the uvula resumes its ordinary length."—*Chelius's Surg.*, vol. i., p. 167. It often becomes very red, elongated, and swollen in the course of an hour, and by dropping on the epiglottis, excites a constant hacking cough, and frequently a sense of choking, which may be partially relieved by closing the mouth and breathing through the nostrils.

Dr. PARISU, of Philadelphia, has recorded two cases where the voice underwent a peculiar change from the excision of the tonsils. Here the voice was rendered shrill and whistling, and we have observed the same modification in other cases from the same cause.—*Trans. of the Coll. of Phys. of Phil.*, Nov. and Dec., 1841, and Jan., 1842.]

60. c. The treatment of organic lesions of the throat and tonsils consists chiefly of the early opening of abscesses or small collections of matter when these form, as stated above (§ 42, 43); of the employment of the local and constitutional means already advised when the tonsils remain enlarged and indurated; of the fumigations and washes, astringent, tonic, and antiseptic, when ulceration, softening, &c., affect any portion of the throat; and of the several means above directed, and the diet and regimen recommended for the asthenic and chronic forms, and for the usual consequences of guttural inflammations. In all cases, support of the constitutional powers, attention to the state of the bowels and kidneys, to the digestive functions generally, and to diet and change of air, are most important. Air, food, and water, are influential both in producing and in removing affections of the throat, whether functional or structural; and upon a judicious attention to, and avoidance or selection of these, appropriately to the nature of each affection, the success of treatment will mainly depend.

CLASSIF. — III. CLASS, I. ORDER (Author in Preface).

1. DEFIN.—Numerous white curd-like specks or exudations on the tongue and insides of the lips, gradually spreading to the interior of the cheeks and fauces; preceded and attended by fever or constitutional disturbance, and very often symptomatic of disorder of the digestive organs, or of structural disease.

2. *Thrush*, or *Aphthæ*, was divided by Dr. M. Good into three varieties: 1. *Aphtha Infantum*; 2. *A. Maligna*; 3. *A. Chronica*. The first and second differ chiefly in the degree of vital depression by which each is attended. The third variety is always symptomatic, generally of structural disease. The first has been considered as a primary or idiopathic affection by some writers, but this may be viewed as somewhat doubtful, for it is very generally preceded by disorder of the digestive functions, and by more or less constitutional disturbance; and hence it may be viewed as contingent upon, or as a peculiar manifestation

of, such disorder. It has been often mistaken for, or confounded with, the erythematic, the pseudo-membranaceous, and the ulcerated forms of STOMA-TITIS (see that article), from which it is quite distinct. In the true thrush there is neither pustulation nor ulceration, but an exudation, at numerous points, of a white, curd-like matter, enlarging and spreading more or less along the buccal, pharyngeal, and œsophageal mucous surface.

3. i. CAUSES.—This disease may attack all ages, but with a very different degree of frequency. It is most common in infants, especially those at the breast or only a few months of age. In these, particularly in the two first months of existence, it has been viewed as an idiopathic affection. However, this view is merely conventional, and may be entertained in respect of this affection with a considerable share of justice. M. VERON believed that this disorder may even affect the fœtus. I am not, however, aware whether or no it has been seen in any case at the time of birth. It is rarely observed in adults, and still more rarely in aged persons. When it occurs at a more advanced period than that of early childhood, it is generally symptomatic of, or at least complicated with, some visceral disease. It occurs most frequently in children of a feeble constitution and in those who breathe an impure air. The seasons have no very manifest influence in causing it. M. VALLEIX, however, considers it to be most prevalent in hot seasons. VAN SWIETEN says that it is rarely met with in very cold and very warm climates, but apparently from insufficient evidence. M. GUERSENT remarks, that in temperate countries it is somewhat more frequent in cold and wet seasons, and when catarrhal affections are most prevalent. This seemed to be the correct opinion; but the crowded or ill-ventilated wards of lying-in, or children's hospitals, and even such wards, however well aired; low, humid, and close apartments and localities; insufficient, unwholesome, and inappropriate nourishment; and whatever impairs the vital powers, are the chief causes of this affection, especially in children. Hence it is frequently observed in those who are attempted to be brought up by hand, or who have sickly nurses with poor or unhealthy milk; in the children of ill-fed or drunken mothers, and in those who are suckled by nurses with inflamed and irritable nipples. BOERHAAVE attributed the affection to protracted suckling in many cases, and to the prematurity or improper use of purgatives. It does not appear to be infectious or propagated from one child to another, although it may be produced in more than one by the unhealthy state of the nurse's breast or milk.

4. ii. SYMPTOMS.—According to M. VALLEIX, the thrush is very often preceded by erythema of the groins and the posterior and upper parts of the thighs, which may have existed several days before the affection of the mouth appears. This is certainly the case in many instances, and is an indication of irritation, or a disordered state, of the digestive mucous surface, the circulating fluids being also imperfectly elaborated, or containing excrementitious elements. At the commencement of the complaint, redness, dryness, and heat are perceived in the mouth, and the infant evinces pain, fretfulness, or restlessness, or even disinclination to seize the nipple when applied to the breast of the nurse. At this time, dryness of the skin, frequency of pulse, and various other febrile phenomena are present. This may be called the

first or erythematic period of the disease, and is almost identical with erythematic stomatitis—*Stomatitis erythematica*. (See STOMATITIS, § 3, *et seq.*)

5. *A. The characteristic features of the disease, the eruptive or second stage*, is shown by whitish points or minute white specks in the surface of the inflamed membrane. These specks first appear on the point of the tongue and on the insides of the lips and cheeks. They soon increase in number, enlarge, the nearest uniting and forming irregular but thin small patches, which remain separate or distinct, are after a time detached, and again renewed. As long as these minute albuminous exudations continue distinct—*aphtha discreta*—the complaint is comparatively mild; but they are successively thrown off in thin flakes, the inflammation subsiding at periods varying from seven days to three or four weeks. In severer cases, however, the patches of albuminous exudation increase in size and thickness, unite or run into each other, forming one continuous coating; and extend over the tongue, fauces, and pharynx—*aphtha confluens*. In these cases, the cream-like albuminous exudation covers the greater part of the mouth and fauces, becomes daily thicker or deeper; and, when it is thrown off, the mucous surface, deprived of its epithelium, reproduces a new exudation, softer and more curd or cream-like than the former. The colour of this is at first white, but it becomes yellowish in the course of a few days, the child being more and more enfeebled and emaciated. The pulse is now quick, weak, and small, the stomach irritable, the bowels disordered, and emaciation increased. Subsequently vomitings occur, the matters ejected being mucous, curdy, and of a yellowish or greenish tint; and the substances taken into the stomach being hardly changed. Diarrhœa often supervenes, with extreme prostration; but death sometimes takes place before diarrhœa becomes apparent or at least urgent, owing to the severity of the gastric symptoms, to the impossibility of deglutition, and the rapidly progressive exhaustion. In these cases the surface of the œsophagus, stomach, and duodenum presents a similar appearance to that of the mouth and throat, the villous coat being covered by numerous dirty, grayish, or yellowish elevated specks or patches of exudation; and the villous and sub-villous cellular tissue being injected, tumid, softened, and most readily torn or detached from the muscular coats. When diarrhœa takes place and becomes urgent, and especially if termina, straining, or dysenteric symptoms occur, the aphthæ disappear, almost or altogether from the mouth, the vomitings frequently cease, and food is sometimes even taken and retained. But the evacuations are frequent, painful, mucous, or curdy, sometimes streaked with blood, or contain shreds of lymph or exudation, and are often offensive or emit an acid odour. Excoriations appear at the anus, the sphincter being irritable and constricted, and miliary pustules occasionally break out in different parts of the body. Although in these the duration of the disease is protracted, the ultimate result is not much more favourable than in the former class of cases.

6. *B. After death* the small and large intestines present the most marked indications of change; the appearances of these viscera, as well as the symptoms during life, showing that the disease which had originated in the mouth had traversed

the œsophagus, stomach, and the whole intestinal canal, the upper portions of this canal having been more or less restored to a healthy state after the lower portions had become affected. The bowels are covered interiorly by a pulpy exudation, more marked in some places than in others, and of a yellowish gray or brown tint. The villous and sub-villous tissues are tumid, softened, and very lacerable, the epithelium being thickened and opaque. Whether the morbid exudation be external to, or beneath, the epithelium has been a subject of discussion. According to my own observation, it appears to take place beneath this covering in some situations, especially in the mouth and at the anus, where the epithelium is more fully developed, and above or externally to it in other situations, and to be attended by a thickening or a detachment of the epithelium in most places.

7. *C. The nature of Aphthæ* has been discussed by several recent writers referred to hereafter. Aphthæ is so very closely allied to the plastic forms of stomatitis and cynanche, as to warrant the opinion that it is merely a modification of these, resulting from the age, constitution, strength, habit of body, &c., of the patient, in connexion with the extrinsic causes and influences producing it. According to the ages, habit of body, states of the circulating fluids, and to various external influences, aphthæ, the allied affection, named muguet or blanchet by French pathologists, plastic stomatitis, pseudo-membraneous cynanche or quinsy (the diphtherite of BRETONNEAU), and croup, are merely varieties of one disease marked by different grades of acuteness, by the sensible qualities of the morbid exudation which chiefly characterize them, and by the parts on which this exudation appears, and to which they severally are most prone to extend. While aphthæ, muguet, and plastic stomatitis, on the one hand, most frequently occur in infants at the breast, oftenest arise from intrinsic causes, and most frequently extend to the alimentary canal; pseudo-membraneous cynanche and croup, on the other hand, more frequently affect older infants and children, oftenest proceed from extrinsic causes and influences, and most frequently extend to the respiratory passages.

8. *Muguet or Blanchet*, which several writers have considered as a distinct affection from aphthæ, and from plastic stomatitis and cynanche, is merely a modification of these; or it holds an intermediate place, approaching very closely to aphthæ in its sensible characters, and in its marked disposition to extend along the alimentary canal; and presenting appearances allied to the plastic or pseudo-membraneous forms of stomatitis and cynanche, especially as respects the morbid exudation, as seen in the mouth, or in other parts of the digestive tube. Thus the variety of these affections, termed *Muguet* by French pathologists, may be placed between aphthæ and plastic stomatitis, with which, as well as with pseudo-membraneous cynanche and with croup, it presents very intimate relations.

9. All the affections now named are to be viewed not merely as simple inflammations of the mucous surface or membrane in which they are seated or to which they extend, but also as special or peculiar in their states or characters, particularly in the superficial nature of the inflammatory action; in the plastic condition of the morbid exudation, varying, however, in consist-

ence, cohesion, colour, &c., in each affection; in the manner in which the epithelium of the affected surface is involved in the exudation; and in the marked disposition they all possess to extend along the mucous surfaces, without materially affecting subjacent tissues. These characteristics, especially the disposition to extend continuously, and the states of the morbid exudation, may be ascribed to impaired, or originally deficient vital power, allowing the extension of the morbid action; to an imperfect power of limitation or vital resistance; and to the condition of the circulating fluids, these fluids abounding most probably in albuminous and imperfectly assimilated elements and materials, and being deficient in hæmotosine or duly developed blood-globules.\*

10. *D.* Recent microscopic observers have detected in the cream-like exudations of aphtha, especially in the advanced and most unfavourable states of the malady, when vital power is most depressed, *parasitic vegetable productions* of the most minute and lowest forms. These parasitic formations appear during life in these states of the disease, or immediately after death; and when they form during life they multiply remarkably after dissolution. They can be viewed only as the evolution of the lowest grades of organization in the morbid secretions which take place from surfaces during the most depressed conditions of vitality, and upon the departure of the vital manifestations from the several textures of the body; their multiplication taking place with remarkable rapidity, especially on the more exposed surfaces. They belong to the class *Cryptogamia*, and are low forms of *algæ* and *fungi*. These, which appear on the mucous surface of the mouth and digestive canal, are chiefly the following: 1st. *Oidium albicans* (BERG, VOGEL, ROBIN); *Aphthophyte* (GRUBBY); the *cryptogamia* of aphtha and diphtheritis. 2dly. *Sarcina ventriculi* of GOODSIR; the *Merismopædia ventriculi* of ROBIN. 3dly. The *Leptothrix buccalis* of ROBIN; *algæ* of the mouth. 4thly. The *Cryptococcus cerevisiæ*, KUTZING; the *Torula cerevisiæ* of authors; the yeast-plant. Of the opinions lately entertained as to the formation of these and other parasites some notice will be taken when those which form in *TINEA* are mentioned.

11. II. TREATMENT.—The means commonly resorted to by the ancients for this disease were in many respects the same as those employed in the present day.—*A.* CELSUS advised alum in honey as a local application for aphtha; and AVICENNA subsequently, and LINDT and STOLL in modern times, recommended the same. Honey, myrrh, crocus, and various detergents were prescribed by PAULUS ÆGINETA; and aromatic tinctures with honey, by RIEDLIN. Borax and other detergents were employed, in mucilage, by ACKERMANN, in honey by GOOCH, with cinchona, in hon-

ey by LOEFLER, and in sirup of roses by STARKE. Camphor was used locally in honey by AVICENNA, and the sirup of mulberries by RIEDLIN. The pomegranate fruit and bark were also employed locally by ACTUARIUS; the sulphate of zinc was similarly prescribed by REIL and HERZ. Emetics were recommended by HUFELAND; and when the sulphate of zinc is used locally with honey or sirup of roses, a portion of it is sometimes swallowed and acts as an emetic. Absorbents were mainly relied on by HARRIS and CHALMERS; and the mineral acids, chiefly the hydrochloric, by GRANT and many others.

12. *B.* The treatment of aphtha should be *hygienic and medicinal*—local as well as constitutional or general. Unless *hygienic* measures be judiciously prescribed, the local and general medicinal treatment will generally be inefficacious. The *causes* which have produced the complaint ought to be removed as completely as possible, and the patient placed in a dry, temperate, and open situation in a well-aired apartment. Change of air is in most cases more or less beneficial. The nourishment should be prescribed with care; and if the child be still suckling, the milk and health of the nurse ought to be objects of particular attention. The age of the milk, the habits and functions of the nurse, and the state of her nipples, require examination. If the nurse have suckled long, or if she be intemperate, delicate, unhealthy, or cachectic; if the catamenia have been present, or if the nipples are sore, another nurse should be obtained. If the child is being or about to be weaned, it may be necessary to defer the weaning for some time, if the nurse be healthy; but if the complaint be then or at any other time attributable to the state of the milk, another nurse must be immediately sought for. If this intention cannot be accomplished, or if the child have been weaned, the disease having been occasioned by the change of nourishment, or by improper food, ass-milk or goat's milk, warm from the animal, should be given in quantity or states of dilution, which the peculiarities of the case, or the effects produced, will suggest.

13. *C.* The medicinal treatment, local and constitutional, must depend chiefly on the causes of the affection, on the age, strength, and circumstances of the patient, and on the history and complications of the case. In most instances of this disease, local as well as constitutional remedies are required, the former to correct or remove the local affection, the latter to improve the strength and the digestive and nutritive functions. Washes and lotions for the mouth, to be used by means of a piece of sponge firmly attached to a stick or whalebone, when the child is too young to rinse the mouth with them, are generally required; but the selection of these should depend much on the peculiarities of the case. The biborate of soda conjoined with honey is most commonly used. When the biborate is freely employed it readily cleans the mouth, separates the morbid exudation, and destroys the parasitic production that often appears; but if much of it be swallowed, it irritates the stomach and bowels. If these be already in a state of irritation, the local means which are least likely to increase that irritation or most likely to remove it ought to be prescribed. In such cases weak solutions of chloride of lime, or chlorinated soda, or chloride of zinc, may be used as now advised; or a solution of the nitrate of silver, applied by a pencil

\* [The *Aphtha adutorum* of BATEMAN is a distinct disease from the above, being vesicular, and usually appearing on some of the same parts as the thrush of infants, particularly the edges of the tongue and fauces. If the vesicles be observed before the cuticle is ruptured, the fluid they contain is generally found more or less coloured with sanguineous discharge from the denuded cutis; but when they become broken, the collapsed cuticle exhibits a whitened appearance and adheres to the affected surface, thus exhibiting some resemblance to thrush. The diseased surface is very irritable and tender, and superficial sloughs, to which the cuticle becomes attached, are formed, which do not readily separate. A viscid, offensive discharge takes place, and often excites considerable nausea or vomiting.]

or sponge, as already recommended; or mucilage, or honey, or sirup of roses containing diluted sulphurous or muriatic acid, may be employed in a similar manner. The chief objection to these latter is, that when they are swallowed in any considerable quantity they often occasion severe griping pains, or increase existing disorder of the bowels. Dilute pyroligneous acid with minute doses of creasote may be tried in the same way as the preceding, or lemon juice may be substituted for the acid. Dr. JENNER has recently recommended the solution of a drachm of the sulphite of soda in an ounce of water, as a wash for the mouth when the parasitic formations are developed. Many years ago I generally directed at the Infirmary for children a confection composed of powdered liquorice root, honey, and a small proportion (about  $\frac{1}{2}$  to  $\frac{3}{4}$ ) of spirits of turpentine; and my experience has convinced me of its superiority over other means in the larger number of cases.

14. Various other washes or gargles for the mouth have been advised and are very commonly used, especially solutions of borax with tincture of myrrh, honey, or sirup of roses; or the solution of alum in the infusion of roses, with tincture of krameria or catechu and a small quantity of tincture of opium. If the bowels become much relaxed, the cretaceous mixtures, with the compound tincture of camphor and the tincture of krameria or catechu, and aromatic confection; the warm bath or semicupium, salt or mustard being added to the water, are commonly of service. If the powers of life are much depressed, warm stimulants should be added to whatever other means may be required. Of these the most beneficial are the carbonate and aromatic spirit of ammonia, camphor, capsicum, tincture of cinnamon, or of arnica, or of cascarrilla, &c.; and one or more of these may be selected. If the bowels be constipated, magnesia and sulphur, rendered palatable with ginger and liquorice powder, may be prescribed, either with or without rhubarb, according to circumstances.

15. In all cases of thrush, the *hygienic* treatment ought to receive especial attention. The food of the child should be selected with care, and the effects of each particular article of diet carefully observed, in respect of the functions of digestion and defecation. The other means already noticed under this head (§ 12) should receive no less attention; for the use of detergent, astringent, or antiseptic applications, as above advised, ought never to supersede hygienic measures, the restorative, tonic, and febrifuge remedies, and even the more active stimulants, which are often indicated in both the more simple and the complicated forms of this disease.

[*Aphthæ* should be regarded as one of the varieties of *stomatitis*, which assumes various forms, according to the nature, degree, and seat of the inflammatory action; as *erythematic with altered secretion* (*muguet*), *follicular* (*aphthæ*), *ulcerous*, *gangrenous* (*cancrem oris*).

The *erythematic* variety to which new-born infants are so liable, from the naturally congested state of the buccal mucous membrane, is characterized by redness, heat, and sometimes dryness of the mouth and tongue. It is the first degree, or primary symptom, of the other varieties of *stomatitis*; varying much in intensity and duration; often accompanying inflammation of the stomach

and bowels, rarely giving rise to any febrile derangement in very young infants. The inflammation may be confined to one part of the mouth, or occupy the entire cavity, sometimes spreading to the lips, causing them to tumefy, excoriate, or become the seat of *herpes labialis*. It generally yields readily to emollient gargles, milk diet, and a little magnesia.

*Stomatitis*, with altered secretion, or *muguet*, is sometimes confounded with *aphthæ*, from which, however, it is quite distinct. True *muguet* is characterized by a concretion of mucus on the surface of inflamed mucous membranes, as in the mouth, œsophagus, stomach, and small or large intestines. It occurs under three forms: 1st, in the form of very small white points, dispersed over the tongue and sides of the mouth; 2d, of various-sized shreds; and, 3d, of a distinct membrane covering the tongue or sides of the mouth. In all these forms, the appearances are owing to an erythematic inflammation of the surface of the tongue, or buccal parietes, and the preceding varieties are owing to the degree of inflammatory action present. The slightest grade produces the small white points; as it increases in severity, these points coalesce, and form small laminæ either on the surface of the tongue, or of the lips and cheeks. These layers may thicken, exfoliate and detach themselves, leaving an inflamed surface, which soon secretes materials for a new concretion, which will be renewed as long as the inflammation lasts. This last form is called *confluent* or *malignant muguet*. The pointed variety usually occupies the extremity and edges of the tongue, the second appears on the internal surface of the lips and cheek; while the membraniform occurs at the base of the tongue and on the velum. This affection is almost confined to early infancy, and is extremely apt to occur wherever children are crowded together, in badly ventilated places, and nourished with unsuitable food. It is not confined to any particular season of the year, as proved by observations made by BILLARD at the Foundling-Hospital of Paris, where on an average more than one fourth of the children suffer an attack of it. There is no reason to suppose it contagious. It is attended with more or less heat and dryness of skin and thirst, though the pulse is rarely excited. It is sometimes complicated with other phlegmasiæ, as of the digestive organs, skin, lungs, and cerebro-spinal apparatus.

*Follicular stomatitis*, or *aphthæ*, consists essentially in an inflammation of the muciparous follicles of the mouth, which in the healthy state are invisible, but when inflamed assume the form of small white or red points, with sometimes a prominent coloured spot in the centre, and surrounded by a slight inflammatory circle. Like the former varieties, this disease exists in different grades of intensity, from slight enlargement of the follicles, which pour out a white puriform matter, to ulceration of the same. The follicle, when broken, presents a superficial ulcer, with circular elevated borders, and surrounded by a red inflammatory circle; and from it a white pultaceous matter is secreted, which may adhere in the form of a scab, or be detached and ejected with the saliva.

These *aphthæ* may be isolated, as on the internal surface of the lower lip, the frenum of the tongue, the internal surface of the cheeks, &c.; and if they are numerous, they coalesce, and the curdy matter which is poured out forms a con-

tinuous coat of greater or less extent and thickness. It is this appearance which has caused this form of disease to be confounded with *muguet*, in which there is no solution of continuity, and no development of the follicles. Sometimes a brown scab is formed by the secretion being mixed with a small quantity of blood, which is often mistaken for a gangrenous eschar, though the inflammation may rarely terminate in true gangrene; after cicatrization has taken place, scarcely any trace of the ulcer can be seen.

This disease is not, like *muguet*, peculiar to infants, but may occur at any period of life. It is generally, however, met with in feeble, pale, and leucophlegmatic children, and under the same circumstances as predispose to *muguet*—bad nutrition, vitiated air, crowding, &c. While the latter occurs among newly-born children, *aphthæ* are more frequently met with among those who are teething, and its chief exciting cause, no doubt, lies in the anatomical development and increased vital energy of the follicular apparatus at this period.

The constitutional symptoms are usually slight, the pulse is scarcely affected, and there is not much febrile excitement, unless in children a little advanced in age. If the disease, however, extends to the stomach, the child grows pale and thin, is affected with diarrhœa and frequent attacks of vomiting, or acid eructations, and regurgitations of the milk, while the child is wakeful and restless.

The treatment of this form of disease is very simple—a mixture of cream and the white of egg, or powdered gum arabic, placed in the mouth, or a piece of lint dipped in a decoction of flax-seed or slippery-elm, marsh-mallows, barley-water, or milk and water—always attending particularly to the best hygienic conditions.

The above measures, with suitable nourishment and gentle laxatives, will be all that is necessary in the mild form of the disease; but when the *aphthæ* become confluent, acidulated gargles or slightly stimulating applications may be substituted with advantage, as a mixture of barley-water sweetened with honey, to which a few drops of sulphuric acid have been added; equal parts of finely powdered borax or alum and white sugar; a wash of decoction of cinchona or oak-bark, and in severe cases chloride of soda in the proportion of ʒss. to ʒiij. of water.

The other forms of stomatitis are, 1st. *The Ulcerous*; 2d. *The Pustular*, and, 3d. *The Gangrenous*. The first, the result of ordinary inflammation, and occupying indifferently every part of the buccal cavity; the second developed only during the progress of small-pox; and the third being the termination of any of the preceding kinds of stomatitis already described, but which is more particularly treated of under that head.]

CLASSIF.—See SKIN—Classification of its Diseases.

1. DEFINIT.—A specific chronic disease affecting chiefly the hair follicles, where specific parasitic plants are developed, and which are capable of communicating the disease to parts susceptible of the infection.

2. M. BOSQUILLON supposes that the term *Tinea*\* was used for the first time by ETIENNE, of

\* [The word *tinea*, according to LOVEY, is a barbarous term, introduced by the writers of the Middle Ages, and is supposed to be derived from the words *sahafate* and *alothathim* of the Arabians. Under these names AVICENNA described an ulcerating and crustaceous disease of the hairy scalp, of which he admitted two species, the one moist (*pseudo-tinea*) and the other dry (*favus*, of the moderns). From the Arabian words above alluded to, the commentators and Latin translators have, by abbreviation and corruption, been able to forge the terms *thius*, *thineum*, and *lineam*. MERCURIUS, however, states that the name *tinea* has been given to the malady in consequence of the ravages which it makes on the hairy scalp, similar to those which the insect bearing the same appellation, *tinea* (moth), produces in clothes.—Ed.]

Antioch, who, in 1127, translated the works of HALY HABBAS. It was afterward adopted by GUY DE CHAULIAC, and long subsequently employed by AMBROSE PARÉ. But from the earliest use of the term, the greatest diversity of opinion existed as to the varieties or forms which the disease presented. GUY DE CHAULIAC recognised five forms of Tinea, which term was used synonymously with *porrigo*; viz., *T. favosa*, *ficosa*, *amedosa*, *uberosa*, and *lupinosa*. AMBROSE PARÉ described three varieties; *T. porriginosa*, *ficosa*, and *corrodans*. Much more recently ALIBERT admitted five species of the disease; namely, the *mucous*, *furfuraceous*, *amiantaceous*, *granular*, and *favous*. WILLAN described six species under the genus *Porrigo*; *larvalis*, *furfuracea*, *lupinosa*, *scutulata*, *decalvans*, and *favosa*. It is obvious that those as well as other writers comprised under the generic term Tinea or Porrigo several eruptions of the scalp which actually were varieties of different diseases. Thus the *Porrigo larvalis* of WILLAN corresponds with the *Achor mucosus* of ALIBERT, a variety of *impetigo*. The *Porrigo favosa* is a true *impetigo* of the scalp, and is the same as the *granular tinea* of ALIBERT. The *Porrigo furfuracea* of WILLAN is the *Tinea furfuracea* of ALIBERT, and is merely *Pityriasis capitis*; the *Tinea amiantacea* of this latter writer being only a more chronic and severe form of the same affection. Thus several varieties of *Eczema*, *Impetigo*, and *Pityriasis* have been arranged under *Tinea*, or its synonym *Porrigo*.

3. It has been recently shown by BAZIN, and farther illustrated by Dr. JENNER, that several affections of the scalp are connected with the development of parasitic microscopic plants. These affections are obstinate, contagious, seated chiefly in the hair follicles, have a tendency to spread in circles, and hence have been popularly called ringworm. M. BAZIN and Dr. JENNER have included under the genus *Tinea* those affections which are attended, kept up, or produced by the development of minute parasitic plants or spores; namely, *Tinea favosa*, *T. tonsurans*, *T. decalvans*, and *T. sycosa*. Of these four species, three only will be considered at this place; the fourth, or *Tinea sycosa*—the *Mentagra* of WILLAN and BATEMAN, the *Sycosis* of numerous writers—has been described under this latter appellation. (See art. SYCOSIS).

4. i. DESCRIPTION.—*A. Tinea favosa*, *Porrigo favosa* of WILLAN and BATEMAN; *Favus* of Drs. A. T. THOMSON, SIMON, and others. This disease most frequently appears on the hairy scalp, but sometimes on other parts of the body. It is characterized by dry, thick yellow crusts, which are, when small, circular, depressed in their centres, and somewhat cup-shaped. A hair is generally seen passing through the centre of each crust. Some of the crusts are generally very small, while others have a diameter of one third of an inch, or even upward. The larger appear in many instances as if formed in concentric rings, alternately yellow and brown, and have an irregular shape or outline, still, however, indicating their origin from distinct centres. The large, irregularly-shaped crusts are pitted on the surface, and, from their resemblance—often, however, very slight—to the divided surface of a piece of honeycomb, the disease has been named *favus*. The margins of the larger crusts are considerably above the level of the surface; while the centres seem somewhat sunk into the substance of the

cutis. Upon carefully detaching the crusts from the surface a distinct layer of epithelium is found beneath them, while a careful examination of the smaller crusts shows a layer of epithelium covering them. The crusts of *Tinea favosa* are remarkable for their thickness, dryness, brittleness, and depressed centres. It is not a pustular disease, but it is sometimes consecutive upon eczema, impetigo, chronic lichen, and herpes circinatus; and pustules are occasionally or sometimes formed subsequently to *Tinea favosa*, owing to the irritation produced by the morbid exudation, and by scratching.

5. The hair, even at an early period of the disease, may be easily pulled out from the centre of each little crust. It subsequently falls out of the diseased parts, and permanent baldness of those parts results. When the disease is developed, or any considerable extent of surface is affected, a peculiar offensive odour, which has been variously described, is generally perceived. This was noticed by JOHN of GADDESDEN,\* in his *Rosa Anglicana*, where he gives the following definition of *Tinea*: "*Tinea est scabies capitis, eum squamis, crustis, pilorum evulsione, colore et odore fædo, et aspectu abominabili.*"

6. The parasitic plant, detected by the aid of the microscope, is different in species, and in the precise situation occupied by it in the several species of the disease. In *Tinea favosa*, as described by GRUBBY, BAZIN, ROBIN, and JENNER, the cryptogamic parasite is the *Achorion Schönleini*. "This plant has mycelium, sporule-bearing branches, and sporules. The sporules are round or oval, and their diameter varies, according to GRUBBY, from 0.003mm. to 0.01mm. The vegetable growth is first perceptible between the layers of epithelium, just at the orifice of the hair follicle; from this point it may spread downward between the hair and its capsule, and upward around and in the substance even of the hair."—JENNER.

7. *B. Tinea tonsurans*—*Porrigo scutulata* of WILLAN, BATEMAN, and A. T. THOMSON; *Herpes tonsurans* of CAZENAVE and *Trichinosis furfuracea* by WILSON—is often mistaken for *Herpes circinatus* of the scalp, with which, however, it is sometimes associated. It is characterized by pallor of the affected part, and by decolorization and brittleness of the hairs. Thin, white, powdery scales surround the bases of the hairs, and cover the skin between them. The affected hairs somewhat resemble "tow," and are remarkable for their bent and twisted shape, and resemblance to the fibres of hemp in colour and appearance. They are sometimes so brittle, that every hair in the affected spot is broken off close to the surface. The diseased patches are generally circular. Crusts form on the patches of *Tinea tonsurans* only when, from neglect, from scratching, or from the application of irritants, they become inflamed.

The parasite in this species of the disease is the *Tricophyton tonsurans*, "and is composed of spores only; the spores, however, are occasionally somewhat elongated and arranged in a linear series. They are round or oval, and their diameter varies from 0.003mm. to 0.01mm. The primary seat of this parasite is the root of the hair. Subsequently it extends up into the substance of

\* He admits the contagious nature of the disease, and supposes it to be caused by depraved humours and bad food, and by transmission from the parents or nurse.

the hair, and even outward, according to BAZIN, on to the skin between the hairs."—JENNER. The spores may be at first confined to the hair follicle. But BAZIN and ROBIN have described and delineated them between the fibres of the hair, which they had split up.

8. *C. Tinea decalvans*.—*Porrigio decalvens* of WILLAN and BATEMAN; *Vitiligo of the Scalp* of CAZENAVE—is characterized by the falling out of the hair rapidly, from one or more circular spots, leaving a smooth bald surface, without crusts, scales, or eruption of any kind. When the bald surface is large, it becomes more irregularly shaped, with scalloped edges, and a tendency to preserve the circular form. The disease may spread over the greater part or the whole of the scalp.

9. In *Tinea decalvans* the parasitic formation is the *Microsporon Audouini*. "This plant is formed of branched filaments, on which the spores are developed. The spores are very small, from 0.001mm. to 0.005mm. The seat of the growth is the outside of the hair, and it forms a sort of sheath around the hair, from the surface of the skin, upward, from 1mm. to 3mm. GRUBBY first described this plant, and its relation to *Tinea decalvans*; and ROBIN says he can confirm the accuracy of GRUBBY's description."—JENNER.

10. *D. For Tinea sycosa*, see *art. Sycosis*. These four species of *Tinea* are especially characterized as follows: *Tinea favosa* is remarkable for its crusts; *Tinea tonsurans* for the discoloration and brittleness of the hair; *Tinea decalvans* from baldness not preceded nor attended by an eruption; and *Tinea sycosa* from inflammation, tenderness, hardness, and suppuration of the hair follicles.

12. ii. CAUSES.—It has not been decidedly shown whether or no the parasitic formations detected in these species of *tinea* are the actual causes of them, or whether they are formed in the course of the disease. Those who espouse the former alternative believe that the spores of these parasitic plants are given off, float in the air, and infect those who are exposed to them. Still they admit that these spores require for their growth a peculiar nidus. Dr. JENNER contends that, as all persons who mix with children affected with *tinea* do not receive the disease, a soil favourable to the growth of the spores previously exists, so that when a spore is conveyed to that soil it is developed and forms other spores, and so spreads and propagates. REMAK applied the crusts of favus to his arm, and having removed them after a time, his skin appeared perfectly healthy; and it was not until a fortnight after that his arm had become diseased. Still this experiment does not prove that the spores contained in the crusts produced the infection, but that the morbid secretion forming the crusts infected the parts to which it was applied, and that the hair follicles, thus becoming diseased, furnished the secretion in which the parasites were developed; and hence the experiment of REMAK favours the latter alternative rather than the former; viz., that the morbid secretions of the crusts having infected the hair follicles, parasitic cryptogamic formations were developed in the secretion lodged between the layers of epithelium and between the hair follicles and the roots and fibres of the hair. Those who believe that the conveyance of the spores from the developed disease to a soil suited to their growth, admit that the soil

exists, and consists of an already morbid state of the hair follicles, caused by debility, scrofula, neglect of cleanliness; and that many persons, especially those thus predisposed, "have in their hair follicles a secretion suited to be the nidus of this plant." But this admission is in truth what I contend for; namely, that the disease, owing either to the strumous diathesis, to constitutional or local debility, to uncleanness, to the lodgment of foul matter, or to the contact of contagious secretions, supervenes in the hair follicles, and the morbid secretion in these follicles produces, according to its especial nature or character, a parasitic formation peculiar to each species of the disease. Thus the parasite is consecutive of disease of the follicle, and not the agent by which the disease is propagated. Dr. JENNER almost admits this while he contends for the agency of the spores, by remarking that "the patient suffering from *tinea* comes under our care for the perceptible disease, and will be well contented if we can cure him of that; but it would be better if we could also destroy the susceptibility to the disease—if we could bring the hair follicles into a state in which they no longer secrete a nidus in which the plant can grow." The truth appears to be, that in this disease, as well as in others, where a morbid secretion is produced in states of great general or local debility, and where these secretions remain long in contact with the surface producing it, and protected in these situations, parasitic formations of low grades of vitality and development take place, the morbid secretions forming the material of growth, and the vitality emanating from the diseased part, imparting to these materials the organization which they present.

13. iii. TREATMENT.—General and local debility, a scrofulous diathesis, and want of cleanliness predisposing to, if not of themselves producing, the disease, contagion being an efficient or exciting cause in many if not in all instances, the contagious agent being, moreover, either the spores of the parasitic plants noticed above, or the secretion of the affected parts, the indications of cure are quite apparent. These are, 1st, to strictly observe general and local cleanliness; 2d, to improve the state of the constitution; and, 3d, to remove the local affection. These intentions may be fulfilled contemporaneously. But in many cases, especially of the *second* and *third* species, none of the predisposing causes just mentioned may exist; there may be neither debility, nor the scrofulous diathesis, nor want of cleanliness, and yet the disease is present. Contagion or infection may be inferred without sufficient proof, even although the parasitic formations are detected by the aid of the microscope; for it may as reasonably be concluded that the disease has occurred sporadically, owing to debility or other morbid condition of the hair follicles, the secretion of these follicles giving origin to the parasitic formations in the manner above stated (§ 6, *et seq.*).—A. In most instances, especially where the conditions, often favouring the several species of the disease, are present, frequent ablutions and poultices, in order to remove the crusts; tonics and alteratives, aided by the usual hygienic measures, change of air, exercise, and suitable diet, are requisite. But, at the same time, *local means* are indispensable, especially such as may restore the hair follicles to a healthy state, and destroy the parasitic formations, to which more than due

importance has been imputed since their discovery by microscopic observers. These means are remarkably numerous, but most of them are only occasionally efficacious, comparatively few being even generally successful.

14. *a.* While constitutional treatment is being employed, the local means most to be relied upon should be strenuously continued. The hair ought to be cut close; the crusts of favus softened and removed by linseed or bread and water poultices, and by ablutions with strong soft soap, and the scalp covered by an oiled silk cap. These preliminary measures are always necessary. After these, the local remedies most to be confided in should be prescribed. But, before I notice the substances that have been more recently recommended, I shall enumerate those which had previously been prescribed, and more or less confided in. These latter have generally been employed in the form of *ointments*, of *lotions*, or *washes*, or *plasters*. The first of these, whatever may be the active ingredient, should be washed off by means of soap and water, or any alkaline or detergent lotion, after having been applied for some hours, and immediately afterward renewed; for ointments often become more or less rancid and irritant when they have been long applied. Most of the fluid applications or lotions, whether solutions, dilutions, decoctions, or infusions, require to be applied for some time to the affected part, by means of lint, especially if the crusts have not been entirely removed, and the hair of the diseased follicles is still remaining. *Washes* may be selected with the double intention of cleansing the surface and curing the disease; this latter object being attained either by destroying the parasitic plant or by removing the morbid condition producing the parasite, or by this combined action. *Plasters* may be employed, after the hair has been cut off close to the surface, with the object either of removing the diseased hair, or of curing the affection, or of fulfilling both intentions.

15. *b.* The *ointments* prescribed for this complaint after the crusts have been removed, have often failed. Those containing *mercury* in some form or other, although advised by very eminent physicians, have not only frequently failed, but have sometimes been injurious, especially when their effects have not been carefully watched. Ointments containing calomel are praised by HILDEBRANDT and others. Those with the white precipitate, or with the nitrate, have been employed by PURMANN, VOGEL, LENTIN, MURRAY, and RING. *Sulphur* ointment, or the balsam of sulphur, in the form of an ointment, has been recommended by RULAND, HAMILTON, BARTON, and ALIBERT. Ointments containing the *sulphate of copper* have been prescribed by THOMANN, DESAULT, DUNCAN, and STARKE; that with *muriate of barytes*, by HUFELAND; with *cantharides*, by WENDT; with common *soot*, by PELARGUS, THOMANN, and NIEMANN; with *conium*, by QUARIN, STORCK, MURRAY, STOEHLER, and HUFELAND; with *tar*, by VAN DER HAAR; and with *empyreumatic oil*, by ZACUTUS LUSITANUS and RUDOLPH. The *unguentum Jasseri*, which consists of the sulphate of zinc and sulphur, is praised by SCHACK. It was formerly in great repute in Germany for the cure of this affection. Ointments with the *balsam of Peru* and *tincture of Lytta*, have very often been prescribed by the author for the second and third species of the disease with success.

16. *c.* *Lotions* and *washes* have been as generally used in tinea as ointments. Dilutions of the *acids* have been advised by many—of the *nitric acid*, by COLLA and TOMASINI; of *muriatric acid*, by THILENIUS, PLENK, and BRINCKMANN; of *sulphuric acid*, by AGRICOLA and others; and the pyroligneous *acetic acid*, either alone or with creasote, by myself. Solutions of the *bichloride of mercury*, either in dilute alcohol, or in water with the muriate of ammonia, have been employed by ZACUTUS LUSITANUS, BELL, DUNCAN, and others, but they may be injurious. Solutions of *borax*, either in distilled water or in diluted acetic acid and tincture of myrrh, have been prescribed by the author. Besides the above, solutions of the *nitrate of silver*, of the sub-carbonates of the *alkalies*, of the sulphate of *copper*, of the sulphate of *zinc*, of the sulphate of *iron*, of the *sulphuret of potass*, and of the *arseniate of potass*, have been severally employed by numerous authorities; while decoctions, infusions, &c., of *tobacco* and of various narcotic plants, have been advised by many writers. The *Ledum palustre* was used by LINNÆUS, and the *Tussilago farfara* by MEYER and HUFELAND.

17. The use of *tar-water*, as either a lotion or wash, after the removal of the crusts of favus, is favourably mentioned by WEAVER. I have, in similar forms and circumstances, employed strong *tar-water* with complete success.

18. Other substances have been prescribed for this complaint, either in the form of ointment or in a fluid state, as a lotion or wash, as the peculiarities of the case suggested. Of these the most important are *arsenic* and *tobacco*. My own observation has proved that these may be most dangerous when applied to a large surface after the crusts of favus have been removed, especially when incautiously used in a fluid state, or when ointments containing either have been too long applied or too frequently renewed. IUSTANOND witnessed a case in which the use of a decoction of tobacco was fatal; and I have seen an instance in which arsenic applied to the scalp after the removal of the crusts of favus very nearly produced a fatal result. *Tartar emetic* has been advised by BLIZARD, and employed in the form of ointment and lotion; but it may be also injurious, if not carefully watched, and it is by no means of great service at any period of the disease.

19. *d.* *Plasters* of common *pitch*, or *Burgundy pitch*, have been employed with the object of removing the hair from the diseased follicles, and of restoring the follicles to a healthy state. *Ammoniacum*, made into a plaster with acetic acid, and applied after the crusts have been removed, has been prescribed with the same intentions as the pitch. Tar ointment, or tar mixed with melted suet, has been similarly used. Tar applied simply over the affected part, after the crusts and diseased hair have been detached, and covered by oiled silk, very seldom fails of success, especially if tar or pitch pills be given internally during the treatment.

20. More recently the preparations of *iodine* have been frequently prescribed, both in this disease and in several others of those which I have arranged under the order *Dermatitis contagiosa* (see art. SKIN, § 76). As early as 1825, Mr. MORSON prepared for me an *iodide of sulphur*, which I prescribed in the form of ointment (from ℥j. to ʒj. in ʒj.) in cases of tinea and psora, chiefly at the Infirmary for Children. About the

same time and subsequently, I frequently employed the tincture of iodine somewhat diluted, or the iodurated solution of the *iodide of potash*. These preparations were generally successful, especially if the preliminary part of the treatment was duly attended to (§ 13, 14). I have also employed various combinations of camphor, turpentine, and soap liniment after the removal of the incrustations; or the former of these with lime-water.

21. *B.* When favus is seated on the trunk or extremities, it may be easily cured by these means, or even by alkaline, or sulphurous baths, or by frequent ablation with strong soft soap after the incrustations are removed by poultices. But when it is seated in the scalp, then most of the means above noticed may fail, or at least require a protracted use, if the diseased hair be not removed. *Evulsion of the hair* was long ago directed by ASTRUC, ACREL, FISCHER, VAN DER HAAR, MORISON, LAMOTTE, SEDILLOT, and PLUMBE; and more recently by the Messrs. MAHON of Paris, who facilitated and accelerated this intention by a depilatory powder, the composition of which they kept secret. The method formerly employed of extirpating diseased hair was by applying straps of plaster, variously prepared with pitch, ammoniacum, or other gums, after the removal of the incrustations, and by removing these straps forcibly after a day or two. Dr. WILLIS has justly remarked that any plan of treatment which combines the removal of the hair by gentle means, or when it has been loosened at its roots, with undeviating attention to cleanliness for about two months, will be found to cure favus.

22. Very recently, the local treatment of tinea has very satisfactorily been illustrated by Dr. JENNER, and, in such a manner as to deserve particular notice and adoption. Professor GRAHAM had suggested the use of *sulphurous acid* and the *sulphate of soda* for the destruction of parasitic formations. Dr. JENNER adopted the suggestion in the treatment of Tinea favosa; and it may be inferred that the means he has employed will be serviceable also in the other species of tinea. A solution of sulphurous acid is prepared, by passing a stream of the gas through water until the latter is saturated. Of this solution two ounces may be added to six ounces, to make a lotion, which may be used by means of lint, and frequently applied and kept wet for the removal of the crusts, and subsequently applied to keep the surface clean. Afterward zine ointment may be prescribed to heal the surface left raw or sore by the previous application. I have seen great benefit obtained from washing the scalp occasionally, or frequently, with tar-water, or solutions of creasote, or with terebinthinate lotions. When the disease is seated on the trunk or extremities, the saturated solution of sulphurous acid may be abundantly added to a tepid bath, immersion being continued for about half an hour, and repeated after intervals of two or three days; a very few repetitions of the acid bath appears to remove the disease. This treatment deserves a trial in the second, third, and fourth species of tinea, as well as in several other chronic eruptions, and especially in all those which I have classed under the ORDER *Dermatites contagiosa* (see art. SKIN, § 76, et seq.).

23. *C.* Most of the means above noticed may be employed for the *second and third species of tinea*, due attention being paid to the states of the

hair and hair follicles; and the more stimulating applications, as the balsam of Peru, tincture of lytta, the essential oils, &c., being prescribed in pomades or ointments, after a due trial has been made of the sulphurous acid. After the acid has destroyed the parasite, these applications will be of service in restoring the functions of the hair follicles. (See art. HAIR.)

[We have generally found most cases of this disease curable by removing the incrustations with soap and water, then plucking out the hairs by the roots with a forceps. Apply a solution of *sulphate of copper*, carefully removing the pus by soap and water daily. In a short time the purulent secretion will cease, and the cutis, assuming a red and shining appearance, soon becomes covered with hair. If the copper does not succeed, we resort to the *unguentum hydrargyri nitrati*, diluted with an equal quantity of simple cerate; or the *sulphuric acid* ointment. The *calomel* ointment (3j. to ʒj. lard) we have also found very successful. In several obstinate cases we have succeeded in effecting a cure by first cleansing the head and removing the hair, as above, and then employing the *iodide of sulphur ointment*, made by mixing 16 grs. of sulphur with ʒj. of iodine, and slowly heating over a gentle fire until they are completely fused into one mass, and then made into an ointment in the proportion of 10 grs. to ʒj. of lard, using it night and morning, and gradually increasing its strength from ʒj. to ʒj. Anodyne applications are necessary when the inflammation is attended with much irritability or pain. Constitutional treatment is not to be neglected, and the *cod-liver oil* will be found an admirable remedy, used both internally and externally.]

**TONGUE—DISEASES OF THE.**—(Γλῶσσα, γλῶττα. *Lingua*, Lat. *Langue*, Fr. *Zunge*, Ger. *Lingua*, Ital. *Lengua*, Sp.)

1. Those slighter affections of the tongue which are symptomatic of either constitutional or visceral diseases, and which furnish more or less important indications of the seat, nature, and issue of disease, have been passed in review when treating of the symptoms and signs furnished by this organ in the article SYMPTOMATOLOGY. (See § 101, *et seq.*)

2. I. NEURALGIA OF THE TONGUE.—SYNON.—*Glossalgia* (from γλῶσσα and ἀλγέω, I pain). *Tic Douloureux of the Tongue*.

CLASSIF.—See NEURALGIC AFFECTIONS.

3. A. Neuralgia of the tongue is not of frequent occurrence. I have seen only a few cases; and in these the pain was, without an exception, limited to one or other side of the organ. The pain presents nearly all the characteristics of neuralgia. It is sudden in its accession, most violent, often contracting the organ to the side affected, sometimes causing an abundant flow of saliva, and inducing sympathetically, more or less, contortion of the face. Its continuance may be momentary, its cessation being as sudden as its occurrence; or it may be more protracted, with more or less remission and violent exacerbation. The pain sometimes resembles the passage of a sharp instrument, or of a hot needle from the side of the base to the apex. The cases which I have seen were unattended by neuralgia of any other part, and I have viewed them as indicative of irritation either at the origin, or in the course of the nerves supplying the side of the tongue affected; and as a not improbable precursor either of paralysis of the tongue, or of hemiplegia, or of apoplexy.

4. B. The treatment should be based upon the inferred states of the general and cerebral circulation, as respects either congestion, capillary action, or inflammation. If the neuralgic pain recur frequently, or prove obstinate or protracted, notwithstanding a due recourse to local depletions, especially cupping on the nape of the neck or over the mastoid processes, when general or local plethora or increased action exists; to purgatives and deobstruents, or to tonics, stimulants, and antispasmodics, with or without anodynes, when neither congestion nor inflammatory action is inferred, it will often be of service to pass a seton into the nape of the neck, and to preserve a free discharge from it. In some cases, especially when increased action or congestion exists, the shower-bath or the cold effusion on the head, while the feet are kept warm, or plunged in hot water, ought to be cautiously employed. The treatment in all respects should be the same as recommended in the article on NEURALGIC AFFECTIONS. (See § 79, *et seq.*)

5. II. PARALYSIS OF THE TONGUE.—CLASSIF.—See art. PALSY.

6. i. Palsy of the Tongue is characterized by limited or impaired movements of the organ, and imperfect utterance, or entire loss of speech. The loss of the power of motion of the tongue is gen-

erally unattended by the loss of sensation. The sense of taste is often not affected (SCARPA and myself). Paralysis of motion when primarily affecting the tongue is rarely so complete as to entirely prevent articulation. But after a stroke of apoplexy, or in connexion with hemiplegia or other paralytic states, the motions of the tongue are often so constrained or impaired as to affect articulation, more or less. When articulated sounds are altogether prevented, then the nerves of the tongue are not alone affected, but those also of the pharynx are more or less implicated, deglutition being also impaired, or very difficult. Paralysis of the tongue is most commonly observed at an advanced period of paralysis of a more or less general form, or after repeated attacks, especially of apoplexy, and is a very unfavourable sign. When thus appearing or associated, it is always attended by impaired or lost articulation, and is followed by difficult or lost deglutition; the patient, however, being often carried off by an apoplectic attack before this latter symptom occurs. Palsy of the tongue, in a more or less complete form, rarely precedes apoplexy or hemiplegia; but when it thus appears primarily, or before the occurrence of an apoplectic or hemiplegic seizure, it is always a very dangerous symptom, and most rarely exists long without a severe or fatal attack supervening. When it thus occurs primarily, it may or may not be accompanied by impaired or altogether lost deglutition. I have seen several cases of primary paralysis of the tongue, with complete loss of articulation, the first and most complete of these with Mr. WINSTONE. In these no other sign of disease was observed, and in all I inferred that severe or fatal apoplexy would occur in a short time; this result took place, and was rapidly followed by dissolution. In a case recently attended by Dr. N. GRANT and myself, the paralysis of the tongue and pharynx disappeared upon an attack of gout in the feet. The slighter states of impaired movements of the tongue are, however, no infrequent precursors of apoplexy or palsy, and generally somewhat impair utterance or articulation.

7. ii. The treatment of palsy of the tongue is in many respects the same as described in the articles APOPLEXY and PARALYSIS, and depends entirely upon the inferred pathological conditions—1st, of parts near the origins, or in the course of the lingual and pharyngeal nerves; 2d, of the blood-vessels and blood; 3d, of the organic nervous system; and, 4th, of the excreting viscera. If a gouty diathesis be inferred; or if gout have been previously experienced, sinapisms should be applied to the lower extremities; *Masticatories* and *Errhines* have been much recommended by HAUTESIERCK and LANGE; a seton or open blisters on the neck, by HELWIG, &c., and active purgatives by RIEDLIN; but these are generally in use.

8. III. INFLAMMATION OF THE TONGUE.—SYN.—*Glossitis* (from γλῶσσα, the tongue).

CLASSIF.—III. CLASS, I. ORDER (see Author in Preface).

9. DEFINIT.—Pain, great swelling and redness of the tongue, more frequently towards its base, and sometimes confined to one side of the organ, with more or less febrile action, the character of which varies with the cause and nature of the local disease.

10. Idiopathic and sthenic glossitis is sometimes a very severe and even a dangerous disease. It is not, however, often met with in practice, al-

though the tongue is much exposed to the usual causes of inflammation. J. P. FRANK saw but one case during a practice of twenty-five years, and during forty-five years he treated only seven cases. I have seen only four cases of this form of glossitis in thirty-five years. Of these, two terminated in suppuration; one only having thus terminated in the seven cases seen by FRANK. The four which occurred in my practice either were limited to one side of the organ, or affected one side chiefly. The cases which were followed by abscess were limited to one side; and the inflammation in all the cases was chiefly seated in the thick part of the tongue. This immunity from the more usual sthenic form of inflammation may be ascribed partly to the muscular structure of, and partly to the abundant supply of nerves possessed by this organ.

11. i. ACUTE GLOSSITIS. — *Sthenically acute Glossitis*.—This disease is readily recognised, as it comes directly before the senses of the physician. *It is characterized by redness, swelling, hardness: an acrid, stinging sense of heat, or a burning pain of the tongue, with either great dryness of the mouth, or a profuse flow of saliva, and the usual symptoms of inflammatory fever.* In proportion to the swelling are the functions of the organ impaired, and the voice, speech, and deglutition affected; the two latter being generally either nearly or altogether abolished in the most severe cases. Sometimes the tongue is swollen to such a size as to press upon the glottis, or rather to prevent the rising of the epiglottis, and to fill up the isthmus faucium and mouth, and threaten suffocation. In other cases, the swollen and inflamed tongue is protruded from the mouth. This, however, is oftener the case in the sympathetic glossitis proceeding from cynanche (see THROAT, *Inflammation of*), and from the excessive use of mercury, when the simultaneous affection of the tonsils, parotids, and parts in the vicinity, and the consequent tumefaction of these, press the tongue outward.

[DR. SALTER has described one form of glossitis, which he calls *erectile*, in which the tongue becomes rapidly and enormously distended with blood, hard and stiff. The swelling is so great that respiration through the mouth is quite prevented, and can with difficulty be performed through the nostrils. Though the congestion becomes so intense that the organ is of a dark black colour, neither mortification nor abscess has been observed to occur. Free incisions give exit to the blood, and the patient recovers. Sometimes only one half of the tongue is affected. In most cases it occurs in persons who are in perfect health, and without any manifest exciting cause. —Ed.]

12. A. In some cases the attack is sudden; and in the most severe cases the tumefaction and the threatened suffocation are such as to place the patient's life in imminent danger. The surface of the tongue is generally covered by a thick mucous coating, or by an exudation of lymph. At the commencement of the disease the sense of taste is very acute, owing to the excited state of the nerves and increased vascularity of the papillæ; but, as the disease proceeds, taste is abolished, owing perhaps to the pressure experienced by the nervous fibrillæ from the turgid vessels, and fluid effused in the structure of the organ, and partly to the thick mucus or lymph covering the inflamed surface. To these are added unquen-

able thirst, great anxiety and restlessness, headache, turgescence of the countenance, swelling and tenderness about the throat, and beneath the maxilla, watering of the eyes; sometimes anxious, pale, or saddened expression of countenance, quickened circulation, costive bowels, and high-coloured urine.

13. The course and termination of the disease are the same as of other inflammations. The malady usually proceeds as above, in a more or less severe form, and generally increases until the third, fifth, or seventh day, when it either subsides gradually under treatment, or terminates in resolution with critical phenomena, particularly profuse perspiration, hypostatic urine, or a copious discharge of saliva, or bleeding from the nose, or accession of the catamenia. If a favourable change does not take place at these periods, the disease may terminate in suppuration or in sphacelation; or it may occasion suffocation or apoplexy, neither suppuration nor gangrene having taken place, but these unfavourable results very rarely occur, unless the disease has been neglected.

14. C. Abscess seldom follows glossitis, owing to the muscular structure of the organ. I have seen only two cases in my practice, in which abscess occurred; and after a free opening was made the parts readily healed. Cases are recorded by EBERMAJER, FRANK, and others of this termination of the disease. Owing to the exudation of lymph into the substance of the organ, considerable hardness and enlargement sometimes remain long after the acute state of disease has been subdued. HILDENBRAND supposes that this change may at last terminate in scirrhus or carcinoma; and in this opinion he appears to be supported by the observations of LOEFLE and ZEIGLER. I believe, however, that cancer very rarely or never supervenes upon sthenic forms of inflammation; malignant diseases of the tongue commencing in a slow and insidious form, and independently of antecedent acute disease. When acute glossitis goes on to suppuration, very serious consequences may result from neglect of this state. When the disease comes under treatment previously to the commencement of suppuration, this result may be prevented; or if it be inevitable, danger will be avoided, by a judicious and prompt method of cure; unless it take place in sympathetic glossitis, or in persons of a cachectic habit of body, or in cases caused by animal poisons taken into the mouth, or by the stings or bites of poisonous insects or reptiles.

15. ii. *Asthenic acute Glossitis*.—A. Inflammation of an acute asthenic character may take place either in a person whose constitution has been exhausted and his blood more or less altered, or in the advanced stage of a malignant febrile malady, as in exanthematous and pestilential diseases, or by the application of such animal poisons or deleterious matters as will be noticed in the sequel, to the tongue or mouth. This state of the disease, especially when occurring from these last-named causes, generally appears suddenly, and proceeds rapidly with great violence. The pain and tumefaction are very great, the inflamed parts being livid, or dark red, or brown, and the accompanying fever being characterized by vital depression, by a very quick weak or irritable pulse, and by signs of progressive contamination of the circulating fluids. Asthenic acute glossitis is seldom seen in a primary and uncomplicated form.

It is most frequently met with as a complication of scarlet fever, of small-pox, of erysipelas, and of pestilential maladies. When it occurs primarily, it may generally be inferred that some foul or poisonous substance has caused the attack. But whether appearing primarily or in the course of another malady, its diffusive nature is manifest. It often extends to the fauces, tonsils, pharynx, surrounding cellular tissue, and neck, more especially when it is caused by animal or other poisons, or by the sting of an insect.

16. *B. The course and termination* of this form of the disease are generally rapid and unfavourable, unless very prompt and judicious means be employed. When it is caused by the contact or inoculation of poisonous matters, the local changes vary with the cause. These changes may consist of tumefaction, owing to the exudation of a dirty lymph or serum, or the affected parts may be livid, or otherwise discoloured, and more or less softened; or they may nearly approach a gangrenous state. In some cases the inoculated poison may so affect the organic nervous and vascular systems, and the blood, as to occasion death in a short time, the changes found in the tongue and adjoining parts being insufficient to account for this result.

17. *iii. THE CAUSES* of acute idiopathic glossitis are chiefly poisonous, chemical, and mechanical agents. Animal poisons applied to the tongue, or animal matter in a state of disease or of decomposition, or the blood or the discharge from foul sores or malignant ulcers, the bites of insects, &c., produce the more severe and asthenic form of the disease. The incautions or accidental mastication of acrid and irritating substances, especially such as are poisonous, as briony or wild vine, the mandragora, the arum and other poisonous plants, have produced glossitis. I saw a case of the diffuse and asthenic form of the malady caused by monk's-hood accidentally masticated. Caustics, acids, and acrid chemical compounds, cauterics; hot and highly-seasoned articles of diet and stimulating drinks; mechanical injuries, as wounds, punctures, or bites during mastication or epileptic paroxysms, operations on the teeth, or for ranula; burns or scalds, the irritation produced by irregular or carious teeth, and the local action of irritating or stimulating substances introduced into the mouth during coma, have severally occasioned glossitis. I saw a case following the introduction of mustard into the mouth to produce vomiting in a case of poisoning by opium. The disease has sometimes been ascribed to the more common causes of inflammation, as exposure to cold in any form, draught of cold water or the use of ice, suppression of the perspiration or of accustomed discharges. SCHEIDEMANTEL states that he saw glossitis follow exposure to cold; STARCK from suppression of the menses, and hæmorrhoids; WENDT from suppressed perspiration of the feet; and DELATOUR from sudden suppression of epistaxis.

18. The above have been viewed as the chief *efficient causes* of this malady; but several of these may be considered as incapable of producing it, without the concurrence of others, either *favouring* or reinforcing them. The chief or most influential *pre-disposing* causes are, disorders of the prima via and digestive organs generally, especially those characterized by the accumulation of morbid secretions and mucous sordes; the gouty, rheumatic, and scrofulous diatheses;

and inflammatory affections of neighbouring parts. VON MERTENS, KEMME, LOEFLE, and others have too strongly insisted upon the occasional relations of these diseases to glossitis. In rare instances the disease has been said to have appeared immediately upon the subsidence of other inflammations. Thus FRANK observed it after an attack of hepatitis; Dr. ELLIOTSON saw it after bronchitis; but such occurrences may be viewed as hardly connected, or as mere contingencies.

19. *iv. SYMPTOMATIC AND COMPLICATED GLOSSITIS.*—Inflammation may attack the tongue consecutively upon inflammation of adjoining parts, as of the tonsils, fauces, gums, and pharynx. This form of the disease not infrequently occurs from excessive mercurial action of the salivary glands, which in some constitutions may be induced by a very small dose of any mercurial (see *art. Poisons*, § 568, *et seq.*). This unpleasant result is sometimes induced by exposure to cold, or to currents of cold air about the head and neck, during or soon after the use of mercurials, or from the suppression of the salivary discharge by these causes. When the tongue is affected from excessive mercurial action, or suppression of the salivary flux, there is generally much more tumefaction than actual inflammation of the organ; the inflammatory action even, when present, possessing much less of the true sthenic or phlogistic character than when the disease appears in an idiopathic form.

20. Glossitis also occurs symptomatically, and forms an important complication, in *scarlet fever* and in *small-pox*. REIL observed it in several cases of an epidemic fever which occurred in the north of Germany near the termination of the last century (*Fieberlehre*, ii., p. 370); and VAN SWIETEN, DELAMALLE, LOUIS, MARJOLIN, and myself, have seen it supervene in the progress of malignant fevers. When thus complicated, glossitis is generally asthenic, diffusive, or spreading, the parts adjoining being more or less implicated, and the danger of the disease thereby greatly increased. I have seen this complication also in ERYSIPELAS, and have adverted to it when treating of that disease.

21. *v. SUPERFICIAL AND PARTIAL GLOSSITIS.*—This is generally a more chronic form of the disease than any of the foregoing. It consists chiefly of an inflammatory state of the villous surface of the tongue, and is much more common than inflammation of the substance of the organ. This is very frequent in young children, consisting generally in an extension of inflammation either to or from the adjoining parts. It is thus very often met with in aphthous affections (see *THRUSH*), in inflammation of the mouth and gums (see *STOMATITIS*), and Cynanche maligna (see *SCARLET FEVER* and *THROAT*, &c.). In this partial and associated form of glossitis the edges of the tongue are chiefly affected, but the whole of its surface may also partake more or less of disease, and the organ may also be swollen. The inflammation may be, moreover, of a specific kind—not only of the kinds just mentioned, but *syphilitic*, with or without ulceration. This state of the disease is even occasionally met with in infants, and has been caused by the affected nipples of nurses. This partial form of glossitis may also proceed from mercurial action. It is attended in this case with more than ordinary loss of the vital cohesion of structure; the edges and sides of the tongue have an inflamed, swollen,

flabby, and unhealthy appearance, and retain the impressions of the teeth, against which they are forcibly pressed by the tumefaction of the organ. This state of partial glossitis sometimes gives rise to fungous excrescences of a soft, flabby, and vascular character, shooting between the teeth, and bleeding on the slightest irritation.

22. Partial or superficial glossitis is much more frequently seen in the course of scarlet fever, small-pox, continued fevers, &c., than the form of the disease noticed above (§ 20) as complicating these maladies in rare instances. It often occurs, also, in the inflammatory affections of the throat, as an extension of these affections (see *ARTS. STOMATITIS and THROAT*); and not unfrequently it is symptomatic of disorder of the *prima via*, particularly of the stomach and liver, arising from the accumulation of morbid secretions. Owing chiefly to this cause, it is sometimes also observed accompanying several acute cutaneous eruptions, as urticaria, &c.

23. vi. CHRONIC SUPERFICIAL GLOSSITIS.—This form may be confined chiefly to the sides or edges of the tongue, or may extend over the whole surface. In either case I have seen it as the chief lesion or affection, while it has been more frequently associated with a similar affection of the gums, fauces, and pharynx. It is a common complication in *scurvy*, and then it is generally removed in due time by the means recommended for that disease; but in other circumstances it is a most obstinate, and often serious, but a rare malady. In some cases, the redness and peculiar raw appearance of the tongue have apparently extended not only to the fauces and pharynx, but also to the œsophagus, and, in some degree, to the villous surface of the stomach. When the disease is confined chiefly to the sides or edges of the tongue, the irritation caused by carious or irregular teeth may have occasioned or prolonged it; but, when it is more general, the digestive viscera are in fault, and, owing to the nature of their disorder, the affection of the tongue varies in severity and duration. In a few cases of this disease which I have seen, the redness, pain, heat, and soreness of the tongue were very much complained of; and they had been of considerable or long duration before I saw them. The gums were also red, retracted from the teeth, and the fauces and pharynx were more or less affected. The surface of the tongue was deprived of its papillæ, was raw and inflamed throughout, acutely sensitive, but the organ was not much swollen, although it was the part more especially affected. Of five or six cases of this disease that I have treated, two went from under my observation after having been some time under treatment without much apparent benefit. The others were also obstinate, but recovery or relief followed the means about to be noticed (§ 36, *et seq.*). One of the cases was imputed to the use of iodide of potassium in large doses. In all, the extreme tenderness of the tongue and mouth, the difficulty of taking solid food, or of masticating any food, the pain on deglutition, the disorder of all the digestive functions, and the occasional irritability of the stomach and bowels, the torpor of the liver, the state of the urinary discharges, &c., had occasioned more or less emaciation, with other indications of cachexia, and shown the relations of the disease. This form of glossitis appeared to have been, in all the cases, symptomatic of prolonged or neglected disease of the di-

gestive organs, more especially of the villous surface of the digestive canal.

24. vii. THE PROGNOSIS of glossitis may be inferred from what has been stated respecting its forms and terminations.—*a.* When the disease has been produced by an animal poison; when the attack is sudden and violent, and the swelling is great; when the constitutional disturbance is very considerable, and the pulse is quick and weak, the disease is then attended by great, or even extreme danger. The risk is generally greater in the *asthenic* than in *sthenic* cases; but, even in the latter, when the tongue is greatly swollen, or much discoloured, and the suffocative symptoms urgent, the danger is then very considerable. In the milder idiopathic forms, especially when the treatment is judicious and prompt, the prognosis is favourable. When the disease is complicated with any of the forms of *cynanche*, or is attended by much swelling, pain, and tenderness about the throat and angles of the maxilla, the danger is considerable, as the extension of inflammation either from or to the tongue indicates both a severe form of disease, and a faulty state of the vital power and habit of body of the patient.

25. *b.* The termination in *abscess*, although an unpleasant occurrence, is not generally attended by danger; indeed, in persons not otherwise diseased, the constitutional symptoms not being very urgent, no risk may be apprehended, particularly if the abscess be limited in extent, or confined chiefly to one side of the tongue. If suppuration, however, take place in an unhealthy subject, and be attended by a very quick, irritable pulse, by depression of the vital energies, by delirium towards night, coma, followed by a fatal issue, should be expected. Sphacelus and gangrene rarely occur, but recovery never takes place when they appear in this organ as a termination of either primary or complicated glossitis.

26. *c.* Partial glossitis and chronic glossitis, especially when affecting aged persons, are often very obstinate diseases; the latter especially. When the partial glossitis is caused by carious or irregular teeth, or has often occurred, or has gone on to ulceration, it is very difficult of cure. The ulcerations may become indolent, or be followed by hardening, enlargement, or even by scirrhus and carcinoma. The tongue may thus present a very dangerous state, which, although at first local, may, in its advanced stages and malignant form, assume a constitutional and fatal character. Chronic glossitis is always a protracted and unfavourable form of disease. In all the cases I have seen, it formed only a part of very complicated states of disease, but a very distressing part, requiring both discrimination and perseverance in both the local and constitutional treatment.

27. viii. TREATMENT.—*A.* OF ACUTE GLOSSITIS.—The treatment of this disease should be modified according to the causes producing it. When it has arisen from causes the operation of which still continue, as the irritation occasioned by irregular or carious teeth, foreign bodies, &c., these should be removed as soon as possible. When it has originated in causes which are not depressing to the vital energies, the means of cure should be very different, or even opposite to those which are required when it is caused by poisonous agents. In the former circumstances the disease presents a *sthenic* character, in the latter an *asthenic* form, both locally and constitutionally.

28. (a) *Sthenic Glossitis*.—In this form the vital energies are not impaired, although vascular action be locally and generally excited. Hence vascular depletions are promptly required, with an activity proportionate to the severity of the disease. Authors, however, differ as to the situation from which the blood should be abstracted. Many recommend the application of a number of leeches,\* or scarifications and cupping, about the throat, angles of the jaws, and neck, after venesection in the arm; others advise blood-letting from the radial veins, or from the feet; while some prefer the application of leeches to the inflamed tongue.† The determination of this matter may be of some consequence, and it may be even next in importance to the amount of blood which should be taken away. In these matters the physician should be guided by the causes and the severity of the disease. But in acute sthenic glossitis, blood-letting, whether general or local, or both, will not of itself cure the disease, unless in its less severe forms; and in those which are severe, the radial vessels cannot generally be reached.

29. The very slight advantage derived from vascular depletion in this disease, as usually performed, has been long known to physicians, and has led them to the adoption of other measures of a decisive character, and productive of a locally depleting effect, namely, of *incisions* made into the substance of the inflamed organ. This practice seems to have been first resorted to by JON MECKREN in 1656, and it has been generally followed ever since. DELAMALLE, NAUMBERG, STÖLLER, J. P. FRANK, ARNEMANN, HILDENBRAND, SCHNEIDER, DELATOUR, VAN DEKEERE, MARJOLIN, and others, have prescribed it in many cases. LOUIS states that *incisions* have failed only in those cases where they have been too superficial, and he therefore advises that they should be deep, and consist of from two to four, made longitudinally near the edges of the organ—one or two on each side of the median line, from the base to near the point. A copious discharge of blood should be promoted from the incisions by emollient applications, by the steam of warm water or medicated vapours, by suitable gargles and washes, &c., which will, at the same time, favour the termination in resolution. In the cases which I have seen, incisions were successfully employed. In two cases, suppuration had advanced before I was consulted, but incisions were directed and were equally beneficial.‡

30. Other antiphlogistic means are also required in this form of the disease, especially cooling purgatives and diaphoretics. Drastic purgatives are often necessary at the commencement of the treatment, and although BROUSSAIS and his followers—the master and disciples of a now obsolete school—have inveighed against them, experience has demonstrated their utility. GALEN, VAN SWIETEN, and many others, have recommended them. Their operation should be assisted by active purgative injections. The excessive thirst accompanying the disease may be calmed

by a solution of cream of tartar, with a little nitre in tamarind water. If deglutition be prevented by the swollen state of the tongue, the urgency of this symptom may be moderated by tepid or warm bathing, by emollient lavements, and by cooling and emollient fomentations to the throat, and by applications to the tongue itself. Injections of a similar nature should be thrown into the mouth, which the patient ought to be directed to gargle or wash frequently with emollient infusions and decoctions. SPERANZA advises an infusion of digitalis for this purpose.—(*Annali Univ. de Med.*, Jan. 1829.) MARJOLIN recommends gargles and lotions with diluted vegetable acids. A solution of the bichlorate of soda and bitartrate of potash, or of the former alone, in the decoction of marsh-mallows, or in linseed tea, is one of the best gargles or washes in this disease. I have employed it with benefit in this form of glossitis, as well as in the other forms which I have designated partial and superficial. Linctuses, consisting of mucilages or honey, or sirup of roses, and containing either the muriate of ammonia or the nitrate of potash, are also of considerable benefit, both in these states of the disease and in the partial and superficial forms.

31. In addition to the above means, external and internal *derivatives* or *revulsants* have been resorted to, as *blisters* or terebinthinate *embrocations* applied beneath the lower jaw, or to the nape of the neck, and repeated; *sinapisms* to the lower extremities, stimulating pediluvia and manuluvia, drastic *purgatives*, and irritating *enemas*, &c. M. DUPONT advised, after incisions or scarifications of the tongue, an active *emetic*; and I believe the practice to be judicious. Among other means, substances calculated to excite the action of the salivary glands have been recommended by BLANCARD and MARCUS. Mercurial preparations may be prescribed for this purpose when the disease is not of mercurial origin, but their action is not sufficiently rapid nor certain. SPERANZA advised lotions of infusion of digitalis.

32. (b) *ASTHENIC GLOSSITIS*, especially when it becomes diffusive, or has been induced by the contact or inoculation of an animal or any other poison, often assumes a very violent and dangerous form, the lividity and swelling of the organ being great, the local and constitutional symptoms indicating a powerful sedative influence on the system. Consequently, a different treatment from that advised above is required, and that treatment should be promptly decided on and energetically carried out. Still the severity and the cause of the disease should decide the adoption and the selection of the means. Vascular depletions, as usually practised, are not required in this form of the disease, and are rarely productive of any benefit. Yet *incisions* into the tongue (§ 29) may even here be practised with advantage. The cases of STÖLLER prove their advantage in this state of the disease. Indeed, incisions may be more advantageous in this than in any other form of the disease, by allowing the discharge of the poisoned exuded fluids, causing the swelling and contamination of the organ. After they have been made, the tongue and mouth should be afterward often washed with a decoction of cinchona, with either of the mineral acids and camphor, or with a strong infusion of green tea, or of arnica, or with strong tar-water; or these ought to be injected into the mouth, when they cannot be otherwise taken into it; and full

\* [Professor WOOD says, "As many as one hundred American leeches may be applied at once, if the strength of the patient permit. They should be preceded by venesection."]†

† [Leeches are better when applied in the vicinity of an inflamed organ than immediately to it.]

‡ [If incisions and the other measures prove unsuccessful, and suffocation is threatened, laryngotomy or tracheotomy should be at once resorted to.—*Ed.*]

doses of the preparations of cinchona, of serpentaria, or of arnica with camphor, or with hydrochloric acid and hydrochloric ether, or with ammonia and its preparations, should be often administered, in such forms and vehicles and in such a manner as circumstances will suggest or require. If an animal poison has occasioned the disease, fluids containing the turpentine, or creasote, or the chlorides, &c., ought to be introduced into the mouth, and the tonics and stimulants assiduously administered, conjoined with alkalies, or with chlorides, or with other medicines already mentioned, both by the mouth and in enemata.

33. *C. Glossitis, symptomatic* of, or complicated with, eruptive or malignant fevers, is generally of an asthenic character. Blood-letting is injurious in these cases, beyond the local discharges proceeding from the incisions, which also may be necessary, and which should then be made, when the tumefaction and pain, or sensation of suffocation, are urgent. While the primary or the special disease ought to receive due attention, and be treated appropriately to its form and stage, the local complication, according as it may present more or less of the characters appertaining to either of the cases above described, should be treated conformably with the recommendations already offered.

34. When the disease has gone on to *suppuration*, then incisions into the adjoining parts, and a free opening into the part in which the matter is either forming or is collected, should not be neglected. If there be little or no swelling unless that produced by the collected matter, a free opening into it will generally suffice. But when the matter is formed in the asthenic form of the malady, or after inoculation or contact of a poison, incision or scarifications of parts adjoining may be required.

35. The severe states of glossitis caused by mercury have been likewise treated by incisions by PLENK, DELAMALLE, FRIESE, SCHNEIDER, and others. LOUIS advises blood-letting, and agrees with PLENK and others in the active administration of purgatives, drastic enemata, sudorifics, diuretics, astringent and cooling washes, and change to a dry and healthy atmosphere. Emetics have also been recommended, and I have prescribed washes with tar-water, with creasote, with the chlorides, and with several other substances, the affliction continuing notwithstanding for a considerable time in some cases. (See *art. Poisons*, § 590, *et seq.*, and *Stomatitis*, § 20, *et seq.*)

36. *B. Partial and Superficial Glossitis*.—Most of the local means already advised may be prescribed in this state of the disease; but in all cases due reference should be had to the predisposing and exciting causes, and to the states of the digestive, the assimilating, and of the depurating functions, and of the constitutional powers. The lotions, linctuses, &c., washes or gargles, mentioned above (§ 32), or those prescribed in the *art. Stomatitis* (§ 14, *et seq.*), or solutions of either of the mineral salts, as the sulphate of zinc, the nitrate of silver, &c., may be severally employed as circumstances will suggest. These last, or the dilute mineral acids in tonic or astringent decoctions, and used as washes or gargles, are most appropriate when ulceration is present. In most of the cases which come under the present category, the treatment and means advised under the heads *Stomatitis* and *Thrush* are quite appropriate.

37. *C. Chronic Glossitis*, whether it be limited to the sides or edges of the tongue, or whether it be more general and superficial, is always a most obstinate disease, and is often merely a severe local manifestation of a very general and serious malady, or at least of a protracted disease of the digestive organs. Hence, in addition to the local means already recommended—to the use of vegetable, of saline, and mineral astringents and refrigerants, of emollients and demulcents, &c.—general and constitutional remedies, directed especially to the restoration of the digestive, assimilative, and depurative functions, or to the removal of whatever lesion or disease which may be inferred to exist in any of the organs devoted to the discharge of these functions, should be prescribed, and their effects closely watched and aided by a suitable diet, regimen, and change of air. Cachectic symptoms should be combated; and when the diet, mode of living, air, water, or residence of the patient appear to have originated or concurred in producing the malady, these especially should all or severally be ameliorated, or altogether changed.

38. The principles now stated and developed above, as well as in other places in this work, must be guides to the inexperienced in the treatment of the diverse forms and complications of glossitis; for it is impossible to lay down rules, or to furnish illustrations or explanations of such rules, as will be altogether appropriate to the diverse cases which may occur in practice. In such cases, as in those of other diseases, the physician must think and decide for himself, and, by thus habituating himself, he will ultimately more certainly arrive at correct practical conclusions.

#### IV. ORGANIC LESIONS OF THE TONGUE.

##### CLASSIF.—IV. CLASS, I. ORDER (*Author in Preface*).

39. The structural alterations of the tongue are consequences either of inflammation, or of unhealthy or cachectic states of the constitution, or of chronic disorders of the digestive organs. Inflammations, either primarily or consecutively affecting the tongue, are rarely of any considerable duration, without changing more or less the structure of the organ; still they cannot be viewed in their earlier stages especially as falling within the category of structural lesions. Cachectic states of the constitution may variously alter the organization of a part or organ, independently of inflammatory action, by either impairing, increasing, or otherwise altering the nutrition of that part, or by changing its cohesion, consistence, bulk, &c.; and prolonged disorder of the digestive organs may sympathetically occasion similar effects on this part. Organic lesions of this organ may, moreover, be produced by specific poisons or infectants.

40. *i. ULCERATION OF THE TONGUE*.—This lesion is frequently a consequence of partial or chronic glossitis, especially when limited to the sides, edges, or point of the tongue. It is often also a result of *Stomatitis* and *Thrush*, and of exanthematous and continued *Fevers*, more especially of *Scarlet Fever* and *Small-pox*. It frequently complicates *Scurvy*; and is often caused by the prolonged irritation of irregular or carious teeth. These antecedents are sufficiently indicative of the nature and treatment of the lesion. But the ulceration may be of a *specific nature*, and, it may be, *primarily*, or *consecutively*, or *secondarily specific*: as such it falls within

the category of VENEREAL AFFECTIONS. Irrespective of these states of ulceration, there are others which not unfrequently are subjects of interest and concern to the physician—which cannot be imputed to these affections, and which require both a local and constitutional treatment.

When ulceration of the sides of the tongue is the result of prolonged irritation of irregular or various teeth, both the nature and the treatment of it is obvious. As a consequence of scarlet fever, small-pox, and fever, the ulceration generally heals with the progress of convalescence. In rare instances, however, it becomes obstinate and chronic, requiring the application of strong solutions of the nitrate of silver, or the bichloride of mercury, of the tincture of iodine, &c. These ulcerations are seldom on the dorsum or middle superior surface of the organ; but, when they are thus situated, the constitutional disorder is then chiefly the cause, unless some local disorder of the surrounding parts have complicated and increased the affection. One of the most difficult cases of ulceration in this situation occurred in a case of typhoid fever, and was manifestly caused by the patient having, in the course of his delirium, taken a tongue-scraper, and forcibly removed the long dark fur covering the tongue; this fur evidently tending to protect the surface of the organ during the advanced stages of the fever.

41. Ulceration of the tongue may, however, take place without very manifest antecedent inflammatory action—at least without any severe or prolonged state of this action, and without any evidence of the state of the opposite teeth being its cause. The conditions of the digestive organs, especially of the stomach and collatitious viscera, or of the system generally, are, in most of these cases, the chief assignable causes; especially when the ulceration does not present either specific or malignant features. In some instances, even when these features may be expected, or are about to be developed, they may not be clearly manifested; for the ulceration may be either indolent, chronic, and variously characterized; and yet it may be difficult to state with certainty its cause, nature, or probable issue—the antecedents, concomitants, or history of the case being the chief guides. An ulcer in the side of the tongue, when caused by the teeth, may be cured with difficulty, even after the cause is removed; and when it has followed protracted disorder of the digestive organs, or a scorbutic attack, it is not readily healed in many cases, after the disorder of these organs, or after a general cachexia, is either removed or greatly ameliorated, especially in aged persons. The dread of consecutive malignancy, or cancerous degeneration, always suggests itself; and, although such a result may not take place, we know that it often has occurred in such cases, or that the cancerous nature of the ulceration does not always distinctly declare itself at first.

42. II. CANCER OF THE TONGUE is not infrequent.—A. Dr. WALSH states that out of 8289 fatal cases of cancer reported in the Paris registers in 1836, it was primarily or mainly seated in this organ. Scirrhus is its usual form, passing into ulcerations; but fungous excrescences sometimes appear, or exhibit the encephaloid character. It may attack any part of the tongue, especially the sides. I have seen three cases where it affected one side chiefly of the thick part or

base of the tongue, extending to the isthmus of the fauces and even to the pharynx, occasioning remarkable dysphagia and its usual symptoms. It may commence as a small, somewhat knotty, and irregular tumour, generally seated in the anterior part of the organ, midway between the raphæ and the edge, or rarely extending beyond the middle line. It sometimes appears as a small excrescence. In very rare cases the cancerous matter is deposited in erectile tumours. Simple ulcers of a chronic or indolent nature may become cancerous; but instances of this occurrence are comparatively rare. In all cases, when the surface ulcerates, the glands become affected in the usual way. Distant organs are not frequently implicated. There is generally an aching sensation in the affected part and vicinity, with occasional sharp or darting pains towards the ear or throat. Pain and difficulty in speaking, masticating, and swallowing are always present, and increase with the progress of the disease, until these functions can no longer be performed. Incessant sputation is always present, and is most distressing. The cancerous cachexia and emaciation are always very remarkable. According to Mr. TRAVERS, strong males, upward of forty years of age, are the most frequent subjects; but the disease is not rarely observed in much younger persons and in females.

43. B. *The Diagnosis* of cancer linguæ is sometimes difficult. The history and antecedents of the case should be duly considered. Cancer may be mistaken for *simple induration* of a part or side of the tongue—an affection noticed by RUYSCH and PERCIVAL, and most frequently seated in the base of the organ. This induration may depend upon tubercular deposits, and be attended by ulceration; but it is not apparently malignant, although it may possibly become so. Mr. TRAVERS has described a *globular tumour* seated deeply in the tongue, which is characterized by an unyielding and uniform surface. Both these forms of lesion are best treated with tonics and alkalies conjoined with the iodide of potassium. The *fissured and dyspeptic ulcer* may bear a near resemblance to cancer, but it has not the hard basis of the latter, is often in the middle line, the rest of the tongue being often chapped or fissured. It is frequently complicated with psoriasis. *Syphilitic ulcers* are not easily distinguished from cancer linguæ. They are generally larger, have less marked and less circumscribed hardness of their margins: their discharge is less abundant, and they want the firm everted edge and sprouting edge of the latter. The history of the case should be strictly ascertained. "Dr. WARREN describes an *enlargement of mucous glands* occurring on the side of the tongue, with a red fungous appearance, but differing from cancer in being sensitive, not painful, and unattended by real ulceration or thickening of the organ. *Hypertrophy of the mucous membrane* sometimes gives rise to irregular fissured elevations on the surface." *Erectile tumours* are known by their pulsation; but they become seats of cancerous deposits.

44. C. *The Treatment* of cancer of the tongue is palliative only in most cases. As the disease often primarily attacks this organ, the removal of it by surgical operations may be attempted before the glands in the vicinity become affected. Successful cases of this kind have been published by Mr. J. M. ARNOT and others (*see the modern Works on Surgery*)

[The *diagnosis* of cancer of the tongue is, like that of other cancers, in many cases, difficult, if not impossible. Even after its extirpation, when we can examine it at our leisure, and with all the microscopic and other aids in our power, we cannot always decide with certainty as to its nature. Our diagnosis is to be based, 1st, on the peculiarity of the development of the tumour and the changes which take place in it; and, 2d, on the presence of true cancer-cells, *viz.*, the *irregular caudate*; the *large cells with many cytoblasts and young cells*; *cells with a thick wall*; and the *accumulations of cells in fibrous capsules*; all of which are readily distinguishable from pus-corporules, or the indefinite cellular structure of tubercle; and in proportion to their abundance, preponderance, and perfect condition, will be the certainty of our diagnosis. It is certain that, before the stage of softening, a correct diagnosis must be founded exclusively on the presence of cancer-cells; and the only successful treatment is the entire removal of the diseased mass by the knife or caustics. It is the nature of every true cancerous tumour to increase continuously; as nature has adopted no means, as in the case of tubercular and other tumours, of limiting its growth. Hence, as we know as yet of no *specifics* for the cure of cancer, the only proper mode of treatment is the *early use of the scalpel*. We need not dwell on the necessity of the entire radical extirpation of the diseased part, whether the knife or caustic be employed, as every one knows that, if any cancerous matter remains behind, it will grow much more rapidly than before, in consequence of the more abundant secretion of cytoblastema. But a radical cure is not to be expected if the surrounding parts are not in a healthy condition, or the original cancerous diathesis is not eradicated. As the diagnosis, then, of a cancerous tumour in the living body is uncertain, it is expedient, in all cases of chronic tumours of the tongue, to extirpate them immediately, and before ulceration takes place; as no harm will occur from the removal of an innocent tumour, while, should it prove cancerous, the worst consequences may result from leaving it till ulceration takes place.]

45. iii. HÆMORRHAGE FROM THE TONGUE rarely occurs unless from accidents or operations, or in the far-advanced stages of diseases especially affecting the crasis of the blood and the vital cohesion of the tissues. In these latter circumstances it is chiefly met with in some extreme cases of mercurial affection of the tongue, and not infrequently in yellow or hæmagastic pestilence, and in scurvy. In these maladies the blood often exudes from the surfaces of the tongue and gums more or less copiously. J. P. FRANK notices a case of the latter disease in which the hæmorrhage was so abundant from the tongue as to prove fatal. For these occurrences, as well as for others of a similar nature, the most appropriate *treatment* is the local application of spirits of turpentine, by means of lint or sponges, while the same medicine is taken by the mouth, in doses suited to the peculiarities and urgency of the case. The other means advised, when treating of *Passive* and other forms of HÆMORRHAGE (see § 40, *et seq.*), may be employed if this fail.

46. iv. INDURATION OF THE TONGUE is rarely met with unless in connexion with tumour (§ 43), or some degree of enlargement. It has, however, been noticed by RUYSCH and PERCIVAL. It is oc-

casionaly seen in some degree in cases of syphilitic contamination. For such, the *treatment* should consist of the means advised for VENEREAL CACHEXIA. In other circumstances the alkalies with iodide of potassium, or the iodide of mercury, or the bichloride of mercury, with conium, may be prescribed.

47. v. ENLARGEMENT OF THE TONGUE, often to a very remarkable degree.—*Hypertrophy and Elongation* have been described by several writers.—A. The enlargement has been generally so great as to cause the protrusion of the organ two or three, or even four, inches beyond the lips, the thickness and the breadth of the tongue being also greatly increased. I had frequent occasion to see a very remarkable case of this kind, many years ago, in a female. The instances of it adduced by ZACCHIAS, BARTHOLINUS, CAMPER, TRIOEN, POILREUX, ARNEMANN, SCALIGER, SANDIFORT, PORTAL, and others, and very recently by MESSRS. HUMPHRY, HODGSON, and TEALE, as well as those described by the writers about to be noticed, present a remarkable similarity as to the appearance and nature of the enlarged organ. This lesion is well illustrated (by plates) and described by Mr. HUMPHRY in the work referred to. The structure of the organ was not altered otherwise than hypertrophied. This disease is quite different from the tumefaction of the organ produced by inflammation or by excessive mercurial action; as it is permanent when not restrained by surgical treatment, and is not occasioned by the causes just mentioned. In the case which I saw the disease commenced in childhood, and had continued without change up to the period when I examined it, when the subject of it was upward of 40 years of age.\*

[*Hypertrophy* of the tongue may be limited to its muscular substance, its mucous covering, or its papillæ. The former variety may be congenital, and we know a family of several children, all of whom labour under it to a greater or less extent. In adults it may occur as the consequence of glossitis, or without any assignable cause. Of the former, Dr. HARRIS, of Philadelphia, has published a case, in a girl, twenty-four years of age, which progressed until the organ protruded four inches beyond the incisor teeth, measuring one inch and three fourths in thickness by six inches and three fourths in circumference; the projecting portion being dense, of a dark chocolate colour, and constantly covered with a thick, tenacious mucus. The part within the mouth was entirely free from disease, excepting the lenticular papillæ, which were about five times the natural size. In another case, reported by the same surgeon, the hypertrophy was congenital, and was attended with unusual shortness of the rami of the lower jaw, with great separation of the incisor teeth (*Am. Jour. Med. Sci.*, vol. vii., p. 17; *Ibid.*, vol. xx., p. 15).

Dr. WELLS, also, has described a case (*West Jour. Med. and Phys. Sci.*, July, 1832) in a girl six years of age, where the tongue, preternaturally dense and rigid, hung down two and a half inches beyond the teeth of the upper jaw, and was more than two inches in breadth. The patient had suffered much from inflammation and

\* [Dr. PAGET mentions two cases of *fatty tumour* of the tongue, one of them 1½ inch long, and another, which he removed, of a *fibro-cellular* nature, firm yet succulent, and forming an obscurely filamentous tissue, abundantly nucleated.—*Lect. on Surg. Path.* Phil., 1854.]

ulceration of the mucous membrane of the tongue. This lesion would seem to be more common in the female than the male, and is most frequently the result of inflammatory irritation. "Enlargements of this kind," says Dr. GROSS, "are sometimes remarkably vascular, being pervaded by plexuses of dilated vessels, and subject to temporary erections from the preternatural influx of blood. Dissection shows that the fleshy fibres of the tongue have lost their normal colour, and that they are converted into a dense, semi-cartilaginous substance, with scarcely a trace of the primitive structure. In some cases the enlargement of the organ would seem to be occasioned by the development of nœvous-like structure."—*Path. Anat.*

Hypertrophy of the mucous membrane of the tongue is usually limited to one or more points, or extends to the whole surface, varying in thickness from the twelfth to the third of an inch, and exhibiting a rough, grayish appearance, the prominence being sometimes divided by deep fissures. There is usually no pain attending it, but the sense of taste is much blunted or entirely destroyed. The papilla may also become hypertrophied from gastric derangement or local injury, and thus form tumours of the size of a pea or larger, of a deep florid colour, resembling cancerous excrescences, but distinguishable from them by the absence of pain and ulceration. In these cases it is the circumvallate papillæ that are enlarged. The epithelial caps of the conical or filiform papillæ may become extraordinarily elongated, so as to be half an inch long (*Salter*.) They are of a dark colour, and look like little brown hairs. Minor degrees of this condition are not uncommon. In some cases the papillæ become atrophied.

Atrophy of the tongue is a rare lesion, but is occasionally met with. It is sometimes associated with inflammatory irritation or paralysis, and may proceed to such an extent as to leave only a dense, whitish mass, with scarcely a vestige of muscular tissue.

The tongue is also liable to congenital malformations, as bifurcation, extreme smallness, nipple-shaped, double, or even it may be wanting. The frenum may be too long, too short, preternaturally thick, and of a dense, fibro-cartilaginous consistence.

Mr. EARLE, of London, has described a peculiar disease of the tongue, consisting in very minute, semi-transparent vesicles, occupying the muscular substance of the organ, elevating sometimes the mucous membrane in the form of little tumours. In one case they grew in clusters, and were so sensitive as to bleed profusely on the slightest injury. The clusters, in some places, were separated by deep clefts, which discharged a fetid, irritating sanies. *Polypoid growths*, which seem to be of the nature of fibrous tumours, or, in some cases, of enchondroma, are sometimes met with in the tongue; also *fatty tumours* and *simple cysts*. The *caneroid* tumours of the tongue, described by Dr. H. BENNETT, would seem to be true cancer.]

48. *B. The Treatment* of this lesion is entirely surgical, and has been successfully conducted by, 1st. Pressure; 2d. Ligature; 3d. Incisions; and, 4th. Amputation. The treatment by pressure has been employed successfully by LASSUS (in two cases), LOUIS, RUMBAUM, CLANNY, FRETEAU, CROSSE, and TEALE. *Ligatures* were employed

by INGLIS, BIERKIN, VAN DER HAAR, MIRALTY, SIEBOLD, EDHOLD, COOPER, WELLS, LISTON, and HODGSON. *Incisions* were practised by ZACUTUS LUSITANUS and SCHNEIDER. *Amputation* was resorted to by PAMARD, FICKER, KLEIN, PERCY, HARRIS (in two cases), NEVERMANN, LEBER, NEWMAN, MUSSEY, PIMPERNELL, SYME, and HUMPHRY. The result was fatal in SIEBOLD's, LISTON's, and SYME's cases. Pressure would therefore appear to be the least dangerous mode of treatment.

**TREMOR.**—**SYNON.**—Τρομός, Greek; *Tremor*, Lat. *Synclonus Tremor*, Good. *Tromos*, Swediaur. *Zittern*, German. *Tremblement*, Fr.; *Trembling*.

**CLASSIFIC.**—4. Class, 3. Order (Good).—I. CLASS, III. ORDER (*Author in Preface*).

**DEFINIT.**—*An involuntary, rapid, and feeble oscillation or agitation of some part of the body, or of the whole body, appearing primarily and without fever.*

1. Tremor has attracted the attention of the oldest writers on medicine. It has been noticed by HIPPOCRATES, CELSUS, ARETÆUS, and GALEN. AËTIUS and PAULUS ÆGINETA have devoted chapters to the consideration and treatment of it; and many modern writers have taken a more comprehensive view of its morbid relations, its symptomatic forms, and of the means of cure.

2. I. DESCRIPTION.—Tremor is very frequently a sympathetic and symptomatic affection. It is, however, sometimes a primary or idiopathic disorder, or one which can be assigned only to the state of the nervous system, or of the nerves supplying the part affected, either at their origins or in their course. The character or form of tremor varies much in different cases, and with the causes which produce it. Thus it may be merely a *slight but quick oscillation*, or a more marked and *rapid movement*, or *to-and-fro motion*; or it may amount to a *violent agitation*. It may present either of these features, and be also a *rotatory* or a *vertical motion*, especially when the head, eyes, lower jaw, or limbs are affected, and according to the muscles which are acted upon. It may, moreover, be only *temporary*, or of short or uncertain duration; or it may be *remittent*, or *intermittent*, or continue a *very long time*, or the *whole of life*, without apparently shortening the length of life. It may, in any of these, be either *general* or *partial*, as respects the frame. It may be a manifest and an important disease, or part of disease; or the patient may not evince any other disorder. In the latter case it may be viewed as idiopathic, or as constituting the complaint; in the former it is generally only a symptom. Although, when symptomatic especially, it varies its character, not merely as stated above, but sometimes still more remarkably, yet the oscillatory form, or to-and-fro motion, is usually preserved. The jerking and tremulous movements, which occur in other diseases, are observed chiefly in CHOREA, in SHAKING PALSY, in ERGOTISM, in BARBIERS, and in HYSTERIA. In all these, however, the abnormal motion is a symptom merely, is often more irregular, agitative, or spasmodic, than in tremor. The motions in this disorder are very quick and very limited or slight in extent, but always passive and usually very chronic, while they are in those diseases more active and acute. But many varieties of tremor, or modifications, are observed, and are to be referred chiefly to the causes of this affection. Tremor is rarely observed when the patient is sleeping, although he often starts in his sleep, and when he moves, the tremor is commonly very manifest. It is also increased after muscular efforts, or even during these; and by mental excitement, especially during anger or any

feeling of temper. Depressing emotions of mind, the abstraction of accustomed stimuli, fatigue, inanition, &c., also increase the tremulous motions, or even extend their sphere in the frame liable to the affection.

3. II. CAUSES.—Tremor may arise from only one cause, or it may be the result of the concurrence of several. The causes which most frequently predispose to it are commonly such as depress or exhaust the nervous energy of a part, or of the whole frame. Of these the most remarkable are original and hereditary conformation, insufficient or improper nourishment during infancy and childhood, masturbation, premature or excessive sexual indulgences and other secret vices, unwholesome air, and the several depressing causes fully considered under the head DEBILITY (§ 6). While many of these causes, especially when their operation is prolonged or excessive, may singly occasion tremor, others more commonly excite it, after the nervous system has become predisposed and susceptible. Of this latter class the most common are fear, fright, or terror; various moral sentiments, as passion, anger, excessive sexual desire, joy, &c.; contusions or injuries, succussions, concussions of the brain, falls, fatigue; excessive or prolonged muscular exertions, blood-letting improperly prescribed, or excessive discharges of blood, or inordinate secretion; the local injuries of nerves, inanition, or the abstraction of accustomed stimuli; and the abduction of animal heat in any way, whether rapid or prolonged. Most of these causes produce merely a temporary state of this affection. Those which follow more frequently occasion more prolonged or even permanent effects, although variously characterized, as mentioned above, especially as respects remissions, intermissions, or exacerbations. Those more influential causes are, the abuse of spirituous and fermented liquors or of narcotics; the excessive use of coffee or green tea; the use of tobacco in any form, especially when carried to excess; the fumes of mercury, arsenic, or lead, or the actions of those poisons in any form or way; various vegetable poisons;\* sexual excesses, inordinate mental exertion, invagination, and the suppression of accustomed discharges, eruptions, &c. The most permanent states of tremor result from old age and the changes in parts, or in the whole of the nervous system from prolonged debauchery and dissipation, and from organic change in or near the origins or course of the nerves, or implicating the nerves of the affected parts. Many cases of tremor of the simplest and most permanent kind present no manifest cause, and can only be referred to the pathological causes just assigned, although many of the changes may be too minute or much beyond our senses to be detected.

4. Tremor has been divided into several varieties by some authors. Thus, J. FRANK has added the following: 1st. The Inflammatory; 2d. The Rheumatic and Arthritic; 3d. The Gastric; 4th. The Atonic; 5th. The Nervous; 6th. The Metallic, or that caused by metallic poisons. Among the other divisions which have been assigned by writers, the following appear the most deserving of notice: 1st. Tremor senilis; 2d.

\* I have at present an officer under my care who was poisoned in the north of India and recovered with difficulty. Although a large and strong-looking man, he has ever since been subject to tremor, which is much increased by and after excitement. The treatment about to be noticed has been employed with only moderate success.

T. *potatorum*; 3d. T. *mercurialis*; 4th. T. *febrilis*; and, 5th. T. *paralyticus*. The subject may be elucidated by a few remarks on these varieties.

5. (a) The *Inflammatory* of FRANK would have been more correctly named the Congestive; inasmuch as the contingent occurrence of tremor is more frequent in congestive than in inflammatory affections of the nervous centres, and is more likely to take place from general or local vascular plethora, and from morbid condition of the blood, than from inflammation.—(b) The *Arthritic* and *Rheumatic* variety of tremor is not of frequent occurrence, and is an occasional symptom, oftener observed, however, during the earlier periods of convalescence from these diseases than during their course, and especially when those diseases have been neglected, or injudiciously treated by colchicum and other depressing agents.—(c) The *Gastric* form of tremor, contended for by FRANK, is of rare occurrence; for although tremor may be often connected with gastric disorder, the former may no more depend upon the latter than the gastric disorder may depend upon the tremor—both states of disorder being merely concurrent manifestations of the condition of the nervous centres or nervous prolongations, either voluntary or involuntary.—(d) The *Atonic* and the *Nervous* varieties of this writer may be viewed as one and the same; for it matters little whether the efficient or immediate cause be debility, exhaustion, atony, or asthenia, general or local, since the effect is nearly the same, although the causes are generally very different or even opposite in their natures.—(e) The *Metallic* and the *Mercurial* forms of tremor are distinctions which may be admitted as serving both to point out the cause and to suggest the treatment; but these terms fulfil this purpose in a very limited and insufficient manner; for tremor may be caused not by mercury only, but also by lead and by arsenic; and even not merely by metallic substances, but also by several vegetable poisons, as by aconite, conium, stramonium, &c.—(f) The *Senile* form of tremor requires no remark. It is in no respect different from the atonic and nervous.—(g) The *Paralytic* is identical with *Paralysis agitans*, and is treated of in the article PARALYSIS. It often varies in character from the slightest tremor to a more violent agitation, as above stated (§ 2).—(h) The *Febrile* is observed chiefly in periodic, and in low or nervous fevers, and especially in the far-advanced stages of these and sometimes of other fevers, or during convalescence from them. In these the tremour is indicative of depressed or of exhausted nervous power, especially of depressed or exhausted organic nervous power, and of some degree of alteration of the blood.

6. Tremor sometimes pertinaciously follows attacks of fever, especially those of a periodic type; and in some instances continues for a long period, even for months, exasperated, however, by exhausting or debilitating causes. A case of this description recently came under my care in a gentleman long resident in India, and often attacked by periodic fever. The tremor had been of very long duration; it was then his only ailment; and it was much increased by exhausting and depressing causes. It was ultimately removed by quinine, and tincture of sumbul. These cases of tremour are oftener met with in persons who have freely lived.

7. (i) The most frequent form of tremor is that observed in *drunkards* and *smokers*, or in

those who indulge in any of the fermented or *intoxicating liquors*, or in *tobacco* or *opium* in any form. In those persons the tremors are most observable in the mornings, or during the intervals between the abuse of any of the substances indirectly causing them, and are chiefly manifested in the extremities, especially the upper. The tremor in such cases may be either simple or associated with illusions of the senses, or with delusions of the mind. In this latter case the disease is essentially that which has been usually denominated *Delirium tremens*, and which I have described as DELIRIUM WITH TREMOR. But in the former, or when the tremor is simple, the affection may vary in its severity and characters, as already stated (§ 2), especially in the intervals between the abuse of the intoxicating agents; for the tremor generally either altogether ceases or is mitigated, as well as the usually attendant feeling of depression, sinking and anxiety, or internal misery, by recourse to the intoxicating cause. Hence the affection is perpetuated or increased, until it terminates in paralysis, insanity, convulsions, or fatal exhaustion of nervous power, with more or less marked disturbance of the excreting organs.

8. (k) One of the most important forms of tremor, although hitherto not mentioned by writers, is that which may be termed the *Hysterical*. It is merely a modification of the atonic or nervous state of the disorder, which may affect equally either sex; while the hysterical occurs chiefly in the female sex, and is a most obstinate affection, owing to its cause, viz., manustupration—a vice which, when once indulged in, is seldom relinquished, until either the mind or body, or more commonly both, are completely broken down. Hysterical tremor is variously manifested, most frequently in the eyes and eyelids, sometimes in the hands or in the motions of the head or lower jaw, occasionally in the lower extremities; and in this last case it is often associated with incomplete hysterical paraplegia. A case of hysterical tremor of the head and another of the lower jaw came under my observation some time ago; the former having been treated by Dr. N. GRANT and myself. In both these the oscillations were horizontal.\*

9. (l) The last form of tremor which I shall notice is symptomatic of *intestinal worms*; and although this form is merely a symptom, and even a rare symptom, of invermination, yet it deserves mention, as respects not merely this cause of tremor, but also the states of the nervous system, which characterize both the primary disorder and the sympathetic affection. In verminous tremor the organic nervous power is both depressed and susceptible of irritation, which is propagated from the involuntary to the voluntary muscles, chiefly of the abdomen and trunk. The few cases of this form of tremor that I have seen, have been in persons from whom either tape-worm or the long round worm has been expelled.

10. III. THE NATURE OF TREMOR may be inferred from the causes and circumstances of its occurrence. Unless when it proceeds from con-

\* A remarkable case of tremor, resembling a pulsating motion, of the muscles of the throat, was some years ago attended by Mr. Liston and myself. The question was whether it was hysterical or aneurismal, as the movements were often synchronous with the contractions of the left ventricle. The hysterical nature of the case became more manifest; and the patient returned into the country, without having allowed us time to observe the farther progress of the case.

gestion at the origins of the nerves of the affected part, and even in such cases also, tremor must be viewed as an indication of impaired power of these nerves, owing either to some change of their most minute organization, or of those parts of the nervous centres in which they originate. That the state of the circulation in the capillary vessels of those parts, or even of the blood circulating in them, as well as change of the structures or tissues in the vicinity, may also occasion this affection, may be admitted, especially when we consider the circumstances in which it occasionally comes under our observation, especially in the last stages of nervous fevers, in various forms of delirium (as the delirium of drunkards), in some cases of poisoning by narcotics or intoxicating poisons, &c. In a few cases of hysteria, and in rare cases of intestinal worms, tremor is a prominent symptom; and in these a sympathetic affection reflected upon some external or voluntary part or parts from the internal seats of irritation—uterine and intestinal—through the medium of the sympathetic or ganglionic order of nerves.

11. IV. PROGNOSIS. — Tremor often furnishes important prognostic indications. When tremor occurs in old persons, it sometimes is the forerunner of paralysis; and when it affects parts already paralyzed, it occasionally precedes returning health. Its appearance in an early stage of fever, or after the cold stage and during the period of increment, is an indication of severe cerebral affection; and in these cases, as well as its occurrence during or after the delirium of fevers, tremor is a dangerous affection. When it occurs in cases of cerebral congestion, it is a serious symptom; but much depends upon the circumstances of the case. In *gouty* and *rheumatic attacks* it is less dangerous, as long as the extremities or voluntary organs are alone affected; but when either disease has retroceded or been misplaced—internal or vital organs being attacked—and tremor appears in these cases, then the danger is imminent. If this affection be slight; if it depend upon excessive exertion, or upon inaction; or if it be of recent occurrence, it may be generally removed with the causes which produced it; but if it occur in habitual drunkards, smokers, or opium-eaters, or in the aged, and especially if it be associated with delirium, or illusions, or with delusions in persons addicted to intemperance, it either is not permanently removed, or if it be alleviated, it usually returns. Tremor is seldom or never cured when it is associated with *paralysis*, or when it appears in the *insane*. Although it is not a dangerous affection when it occurs in *hysterical females*, yet it is most difficult to cure, especially if there be reason to infer that masturbation has occasioned it, or the associated hysterical disorder. It is less serious when it is symptomatic of *worms*. It generally admits of removal when it has been caused by mercury; but it is cured with much greater difficulty when it has been produced by lead or arsenic; and, in many of these latter cases, it is often attended by great danger. Tremor in nervous persons, and in a slight or limited form, may continue for many years, or even to an advanced or very old age, when it is unassociated with any other disorder, and when the functions, both mental and bodily, are not impaired, or even not materially impaired.

12. V. DIAGNOSIS. — Tremor may be mistaken for several complaints, which either nearly re-

semble, or are closely allied with it; or they may be confounded with it, more especially chorea, the cold stage of ague, the formative stage of continued or exanthematous fevers, shaking palsy, delirium tremens, the subsultus tendinum observed in the last stage of fevers, &c.—*a*. In *chorea*, and in some cases of *palsy*, caused by disease of the membranes of the spinal cord, the motions are very different from tremor. In the former disease, the motion is caused by an irregular and frequent jerk, or momentary contraction of muscles, now affecting one part, then another; while in the latter, there is no tremor when the patient does not exert any volition on the affected limb; but, as soon as he attempts to move that part, the movement is often tremulous, uncertain, and imperfect. — *b*. In *shaking palsy*, the tremor or shaking is constant, unless the patient is sleeping, when it is either absent or diminished, and the power of motion is impaired or lost, or nearly so. Sensation is generally but little affected. — *c*. In *delirium tremens* there is more or less tremor, generally of the hands, and often also of the lower extremities and tongue; but there are also illusions of the senses and delusions of the mind, and nervous excitement. But tremor is often caused by intoxicating fluids, without delirium being present; and in cases occasionally characterized by delirium, tremor is often experienced either before or after attacks of delirium, or it may continue during the intervals between those attacks. The cold stage of ague, or the invasion of continued fevers—the former especially—may resemble tremor. But in the cold stage there is a general feeling of cold, which is not present in tremor, while the motions of the former are more active, and more generally manifested in the frame than those of the latter, which are usually passive and limited to certain parts, or at least not so widely extended. — *d*. The *subsultus* of the last and most dangerous state of fevers cannot be mistaken for tremor, as the history of the case, and the nature and seat of the movement, are sufficient to distinguish between them. The tremor of the tongue, often observed in *low fevers* when this organ is protruded, as well as the tremor of the limbs on attempts at motion or progression, occurs only when volition is attempted, and is distinct from idiopathic tremor, which is always present; the former, or symptomatic, being a frequent attendant upon greatly impaired nervous power, and manifested only when voluntary motion is attempted.

13. VI. TREATMENT. — The means of cure should be selected with strict regard to the causes and pathological states occasioning this affection. When it is caused by mercury or other metallic poisons, the remedies advised when treating of these in the articles POISONS (*see* § 568, *et seq.*), and ARTS and EMPLOYMENTS producing disease, should be adopted.\* Under this latter head the

\* [In tremor caused by any of the metallic poisons, as lead, mercury, &c., the iodide of potassium will prove a very successful remedy, especially in connexion with warm sulphur baths, vapor baths, &c. The bath should be made by taking from ℥ij. to ℥iv. *sulphuret of potassium*, mixed with 20 to 30 gallons of water.]

A new method of eliminating metallic poisons from the system, by means of *galvanic electricity*, has lately been introduced into practice, and, it is said, attended with marked success. A metallic bath is insulated from every thing, and partially filled with acidulated water, to convey more readily the electric currents. The patient lies on a seat in the tub, insulated entirely from the tub. When gold, silver, or mercury is in the system, nitric or hydrochloric acid is employed; when lead is suspected, the acid

prophylactic measures that may be employed against the metallic poisons are fully noticed. Sulphur was strongly recommended for the tremors caused by mercury by Dr. LETTSON; and electricity by DE HAEN, MANDUYT, and SIGAUD LA FOND, not only for the mercurial tremor, but also for tremor caused by other mineral poisons. ZACUTUS LUSITANUS advised sulphurous and aromatic warm baths, not only for those cases, but also for tremors produced by other causes. The treatment recommended by most writers for tremor has generally been either empirical, or been based upon the presumed nervous character of the affection. Antispasmodics were prescribed by MARTINI; blisters by MUYS; musk by STARK and BANG; the oxide of zinc by FISCHER; opium by THOMANN; purgatives by RIEDLIN; cinchona and its preparations by BOUCHER and FILLEAU; and the *chenopodium ambrosioides* by J. FRANK.

14. When tremor is occasioned by congestion or plethora of any part of the nervous centres, then recourse may be had to scarifications and cupping, or to the application of leeches, according to the circumstances of the case. If it be connected with gout or rheumatism, the remedies advised for these diseases are appropriate, but those which lower nervous power ought not to be adopted when this affection is symptomatic of these diseases. If it be caused by intoxicating fluids, the preparations of ammonia are generally most efficacious. When it is occasioned by cold, the warm bath, followed by frictions and ammonia, are indicated; and if these fail, cinchona, serpentaria, the calamus aromaticus, arnica, camphor, guaiacum, &c., may be severally employed. If congestion of the brain have occurred from this cause and produced the tremor, the arm or arms are most frequently the seat of the affection, and in this case cupping, leeches, a blister to the nape of the neck, or behind the ears, or even venesection if the patient be plethoric, as advised by SOLBRIG, may be prescribed. Cases have been recorded by ANDRÉ and others, which have recovered by means of a prolonged course of tonics conjoined with purgatives. Tremor may occur in such various, different, or even opposite circumstances and pathological conditions, whether appearing idiopathically or symptomatically, that it becomes impossible to state the means most appropriate to each of these, at least within the limits to which I am confined. In respect of this affection, as well as of most others, the physician must observe closely and judge for himself, selecting and devising his means with a strict reference to ascertained causes, and to inferred changes.

CLASSIF.—1. Class, 4. Order (Cullen). 3.

Class, 4. Order (Good). IV. CLASS, II. ORDER (Author in Preface).

1. DEFINIT.—Unusually quick respiration on slight exertion, short cough, hectic fever, and emaciation: expectoration at first wanting or scanty, afterward varying with the progress of disease, sometimes streaked with blood, or attended by more marked hemoptysis: colliquative perspirations and diarrhœa, or both alternately, generally supervening or hastening dissolution: usually occurring in the serofulous diathesis.

2. PATHOL. DEFIN.—The infiltration of tubercular matter in parts of the lungs; the morbid deposit undergoing metamorphosis, most commonly softening and more complete solution, followed by erosion of the containing tissues, by ulcerating cavities, by successive changes in adjoining parts, especially by vascular congestion, sanguineous exudation or extravasation, or inflammatory action generally limited to the adjoining structure and to the bronchial canals communicating with the tubercular formations.

3. In addition to the above symptoms and lesions characterizing tubercular consumption, there are many others less commonly present, that can be comprised only in a more detailed description of the several forms and stages of the disease. Of these sufficient notice will be taken in the sequel. Some of the topics more fully considered in the articles SCROFULA and TUBERCLES will here receive a passing notice, in as far as they are more especially connected with pulmonary phthisis. The intimate connexion of scrofula and tubercular formation, in all cases, and their actual identity as respects especially their causes and constitutional relations, have been fully discussed under the heads just referred to (see SCROFULA and TUBERCLES, § 112–119, et pluries). It

\* [The additions to the present article will be chiefly found in the Appendix at the end, to which the reader is referred.—*Ed.*]

is therefore unnecessary to advert to these topics in connexion with tubercular phthisis, especially as they will be made apparent during the description of the causes and organic changes of this malady.\*

4. The *forms and states* of pulmonary consumption—of tubercular disease, affecting chiefly the lungs—and the numerous complications or morbid associations, either developed in the course of this malady, as contingent and intercurrent affections, or existing in the frame as latent or as manifest disorders from the commencement, severally require due recognition and diagnosis, and claim the especial investigation and study of the physician. The early aberrations from health which indicate the commencement of tubercular phthisis have been, during the greater part of the period of which my experience is cognizant, either imperfectly estimated or overlooked, while undue attention has been, and still is, directed alone to that which, although fully deserving a due portion of attention, should not receive an undivided investigation—to *physical diagnosis* in the several forms and methods, in which it has recently been paraded, over-estimated, and lauded. Owing to this one-sided study, to the fallacies inseparable from its nature and to those which arise from varying conditions of vital influence and action, from different states of secretion and excretion, from numerous disturbing causes appearing contingently, and from habits of dogmatizing with the view of exhibiting a precision of acquirement and knowledge beyond what has been previously reached, the cultivation, if not the advancement of physical diagnosis, to the neglect of the intimate observation of constitutional and physiological changes, has been generally attempted. Manipulations which strike the senses of the attendants, and more than one sense of the patient—examinations which may be seen, felt, and talked about, have a much more impressive and lasting influence upon both patient and spectators, than the close observation of symptoms and the pertinent inquiries of the profound and comprehensive thinker. The former are lights which the possessor places upon an eminence for his own advantages; the latter are lights intended entirely to benefit the person for whose safety they are employed. The one method strikes and impresses the patient and those around him, the

other is at best but imperfectly estimated, or even altogether unheeded.

5. Auscultation, which is of great service in the progress of phthisis, is much less advantageously employed at the commencement and even during the early stage of the malady. Too great dependence upon, and a too *ad captandum* parade of, this mode of diagnosis, sometimes even with the fussiness and the flourishes of vulgar craft, have tended to the neglect of those states of vital manifestation, of disordered functions, and of vascular action, which, while they indicate incipient or early pulmonary disease, also characterize its forms, and point to the changes in which these forms originate, and on which they continue more or less to depend. The presence or absence of certain sounds on percussion or auscultation, the states of development and of mobility of the several regions of the thorax, both individually and in relation to each other, are all of great importance in themselves, but this importance is heightened when they are viewed in connexion with their causes and with existing conditions of vital manifestation, of morbid function and of vascular action.\*

6. The usual modes of physical diagnosis in respect of tubercular consumption have been sufficiently described, illustrated, practised, discussed, praised, and confided in, since the days of LAENNEC to those of SKODA, which nearly mark the period comprised by my experience; but they have not always been received as immutable truths. What was confided in by the batoned followers of LAENNEC is now disputed by the skeptical followers of SKODA. Doctors proverbially differ; but professed adepts as certainly disagree, and that the disagreement may not be the less marked and continued, the one school misinterpret or misrepresent the dogmas of the other. As among the microscopists, so among many of those who pretend to the greatest powers of auscultation—who split hairs in auscultatory diagnosis—the greatest differences occur, in the early stages of phthisis especially. What is heard by one is often not heard at all, or heard differently by another; belief frequently rendering the sense of hearing more acute and the physical signs more distinct. Not infrequently the adepts—the *specialists* of this malady, the would-be the greatest authorities, the infallible in this department of *speciality*—find evidence of tubercles in the lungs on auscultation and percussion, where none exist, or have existed, or could be detected after death.†

\* [From the various analyses of tubercle given by different authors, it appears that it consists, 1st, of an animal matter mixed with certain earthy salts, the relative proportions of which vary in different specimens of tubercle, animal matter being more abundant in recent, and earthy salts in chronic tubercle; 2d, that the animal matter contains a large amount of albumen (*casein, fibrin, and fat* have also been detected in small but variable proportion as constituents of tubercle); 3d, the earthy salts are chiefly of the insoluble phosphate and carbonate of lime, with a small proportion of the soluble salts of soda; 4th, that very little difference in ultimate composition has yet been detected between recent tubercle and other so-called compounds of protein. VOGEL, however, states that the chemical composition of tubercle is at present unknown (*"Path. Anatomy of the Human Body."* Phil., 1847), and all that is positively known regarding it is, that it is a protein compound. During softening, the same writer states that chemical changes occur, the phosphorus and sulphur diminishing, till at last they wholly disappear. The experiments of SCHERER seem to show that tubercle in different cases presents a different composition, and is not always identical with protein.—(*Simon's Animal Chem.*, vol. ii., p. 478.) It is admitted by all that, in addition to the protein compounds, tubercle contains various salts, fat, extractive matters, and a substance resembling pepsin—the calcareous salts predominating when the tubercles become changed into concretions, leaving but about three per cent. animal matter.—(*Thenard.*)—Ed.]

\* [DR. CAMMANN, of New York, has invented a stethoscope which possesses many advantages over those in ordinary use. In cases of suspected tuberculosis, in which tuberculous deposits are either wanting or are small and disseminated, we are able, by means of this instrument, to make a closer comparison of the respiratory sounds than with the naked ear or the ordinary cylinder. "A disparity, therefore, on the one hand, is in some instances rendered appreciable which otherwise would not be discovered; and, on the other hand, the absence of a disparity and the completeness of the normal characters are more satisfactorily determined than is always practicable without this improved means of auscultatory exploration. It enables the auscultator to study the characters of the respiration in some cases in which it is so feeble as to be with difficulty appreciated by the ordinary cylinder or by immediate auscultation. Its usefulness, in cases in which it is desirable to make nice comparisons with respect to vocal phenomena, is not less than in examinations with reference to respiratory sounds. These advantages render the instrument particularly serviceable, both in a positive and negative point of view, in the diagnosis of pulmonary tuberculosis."—A. Flint.]

† [We fear that sarcasms in regard to the use of the

7. I. As to the ORIGIN OF TUBERCLES, I must refer the reader to that article (*see* SCROFULA and TUBERCLES); but I may here remark that much has been written upon this topic in former days, and at the present time it still remains a "*quæstio vexata*." At an early epoch of pathological speculation respecting it, the formation of tubercles was imputed to impaired vital influence, and afterward to depressed nervous energy. At a more recent period a morbid nutrition obtained credit for the mischief, although it might have been difficult to show how nutrition, however morbid, could have formed what was admitted to be neither organized nor organizable. Then it was attempted by ROKITANSKI and his admirers to describe tubercles as transitions from organized to non-organized formations. Still more recently the origin of this formidable malady was laid in the blood; and if the actual existence of the tubercular matter could not be detected in the circulation by the far-seeing—or rather near-seeing—microscopists, after the most minute search, the elements of this matter doubtless existed. Upon this latter inference they could safely count. Indeed, this part of the conclusion could hardly be denied; for, where vascular assimilation is deficient, the materials for morbid formations must necessarily abound; and the development of such formations will necessarily most readily take place in situations and structures most favourable to the morbid process, and most exposed to the influence of the causes which predispose to, or produce it. When organic nervous power is impaired, vascular assimilation and healthy nutrition must necessarily suffer; and those tissues and organs which are the most disposed by function and organization, and as respects their capillary circulation and their normal secretions, to experience the early effects of these changes, will be the first to manifest disease, and the most likely to experience disorganization.\*

8. Dismissing, however, the consideration of this topic, and referring to what I have advanced respecting it under its appropriate head, I shall now very briefly advert to the constitutional states in which the formation of tubercles in the lungs generally takes place, and with which they are

more or less intimately allied during the greater part or the whole of their progress. These states have been very imperfectly described and distinguished from each other, both in health and in disease; the great difficulty of assigning distinctions, arising from their mixed characters, the manner in which they pass into one another, and the association of temperament, diathesis, and habit of body being often such as to obscure the subject, and to render precise and accurate observation almost impossible. Nevertheless, these states have a more or less intimate relation to the forms or varieties of tubercular phthisis, and should hardly be separated from a due consideration of the influence and *modus operandi* of the predisposing and exciting causes. Certain of these, especially the scrofulous diathesis, and very probably this only, have a most intimate connexion with the pulmonary disease, while others are much more doubtfully, or even are in no ways, related to it. They should, notwithstanding, be viewed in connexion with the causes, the courses, the morbid associations, and the inter-current affections of tubercular phthisis. The imperfect attention which has hitherto been directed to this part of the subject must be my apology for the insufficient discussion of it at this place, my object being rather to indicate than to supply the deficiency: to this latter end precise observation and patient research are altogether wanting.

9. i. *The scrofulous diathesis or taint* is the most common constitutional condition in which phthisis occurs. It is that intimate organization of frame which results from those predisposing causes, referable to the parent and to the infancy of the offspring, and which, with these causes, I have described when treating of SCROFULA and TUBERCLES (*see* § 3, *et seq.*). But although it is most frequently the basis of the tubercular formations in the lungs, whether latent or developed—the soil in which they grow—yet these formations may appear in other conditions of the frame than this, when the predisposing and exciting causes are in energetic or concurrent operation. In this condition, however, the tubercular formations in the lungs are most prone to pursue their usual course, especially after the age of puberty, and before the period of middle age. They may also assume the acute form, especially in the plethoric, and when their causes are more than usually active.

10. ii. *The lymphatic temperament* has been supposed, especially by French pathologists, to predispose to phthisis more frequently than any other temperament or diathesis, excepting the scrofulous. This may be the case, for I am not prepared to dispute it; but if the question be put as to what constitutes the lymphatic temperament, and as to what signs this temperament may be recognised, but few will agree in the answer, or be prepared to answer it at all. This much may be said respecting it, that it is very closely allied to the scrofulous taint or diathesis; that the lymphatic system is prominently developed in persons possessing it; and that the lymphatic glands and serous membranes in those persons are very prone to become the seats of tubercular deposits, whatever may be their complexions or races.

11. iii. *The melancholic, phlegmatic, and bilious temperaments* do not predispose to phthisis. When this malady occurs in either of these constitutional conditions, it is generally caused by

microscope, instead of serving any useful purpose, will only serve to excuse indolence and depreciate the value of physical diagnosis among practitioners. It is in the highest degree important that medical men should be able, if possible, to detect the existence of this disease in its early stages, when, by proper hygienic means, it is often within our control, and no means of diagnosis which furnish any aid towards that object are to be neglected.—*Ed.*

\* [SIR JAMES CLARK, DR. BENNETT, of Edinburgh, and many other writers on this disease, have called attention to the fact that it is usually ushered in or preceded by derangement of the digestive organs, indicated by furred tongue, capricious appetite, acidity and anorexia, constipation alternating with diarrhœa, and that the same symptoms, in a majority of cases, accompany phthisis throughout its progress, becoming more and more violent towards its termination. It is therefore reasonable to believe that, as the nutritive properties of the blood are entirely dependent on a proper assimilation of food, and as this assimilation is interfered with in the morbid conditions of the alimentary canal, the continuance of such conditions necessarily induces an impoverished state of that fluid, and imperfect growth of the tissues. When, under such circumstances, exudations of the liquor sanguinis occur, they are very liable to assume the form of tubercles, and if they are poured into the lungs, there are then produced those changes and that condition called pulmonary tuberculosis. *See a Treatise on the Pathology and Treatment of Pulmonary Tuberculosis, and on the Local Indication of Pharyngeal and Laryngeal Diseases frequently mistaken for or associated with Phthisis*, by J. H. BENNETT, 8vo. p. 130. Phil., 1854.—*Ed.*]

several concurrent influences, and it frequently assumes a very protracted form, or it remains long latent before it is openly and fully manifested. It may then be far advanced, and either assume in this state a chronic form, or proceed rapidly to the usual termination. It is often, however, very difficult to determine the diathesis and temperament of persons labouring under phthisis, especially in its advanced stage; and the comparative tendencies of either temperaments, diathesis, or habits of body, to this disease, have not been ascertained with a sufficient precision to enable me to state any thing with confidence on this topic.

12. iv. *The nervous, the irritable, and choleric temperaments* present no very marked predisposition to phthisis, although this malady may appear in either of these temperaments when the causes are energetic. In these the disease is prone to assume an acute, rapid, and febrile character, or to be associated with bronchitis or laryngitis; and, in the nervous temperament especially, it may, in its early course, present many of the characters of nervous fever, or, in children, of remittent fever. In either of these constitutional states various complications may occur in the progress of the disease, affecting either the lungs or other organs. Although hæmoptysis may take place in either of these, it is not so frequent in them as it is in the sanguineous temperament, or in the scrofulous diathesis.

13. v. *The sanguineous temperament* is probably more disposed to phthisis than those last noticed (§ 11, 12); but it is more especially so disposed when it is associated with the scrofulous diathesis. It is then apt to favour an acute or febrile form of the malady, which is frequently complicated with hæmoptysis, with pneumonia, and various other lesions of the lungs and pleura. As respects this temperament, as well as the others, a more precise observation of phenomena from the commencement to the termination of phthisis, in a wider field of observation than I have possessed, is required to illustrate this part of my subject, and to render it available to practical purposes.

14. II. DESCRIPTION OF TUBERCULAR CONSUMPTION.—In describing tubercular consumption, or phthisis pulmonalis, I confine myself to the phenomena produced by the formation of tubercles in the lungs, although I do not overlook the fact that tubercles often exist in other organs when they are formed in the lungs, especially in young subjects. Of this circumstance notice will be taken in the sequel. Pulmonary phthisis may be viewed as a vital blight, which in the animal kingdom as in the vegetable, affects the circulating fluids by attacking the organs of assimilation and respiration. Numerous vital and physical causes, severally or concurrently, produce this result; while many influences, occasioning either excessive waste or imperfect supply of assimilating or nutritious elements, exert a similar effect.

15. *Phthisis* may present numerous variations in its course. M. Louis states that he has seen it prove fatal within a period varying from three months to twenty years; and the tendency of the disease to cause a simultaneous or successive formation of tubercles in different parts of the system is one of the chief reasons of these variations. I have met with cases, the duration of which has been even much longer than just now

mentioned, and I will make a more particular reference to them in the sequel. The very different or varied occurrences and lesions, which may take place in the early course or advanced progress of phthisis, independently of the influence of *diathesis* and *temperament*, are such as to vary most remarkably the character of this disease. The development of tubercles in different tissues and organs; the progress of tubercular deposit, and the form of tubercles; their softening, and the excretion or absorption of the tubercular and morbid matters; intercurrent inflammations, bronchial irritations, or pleuritic attacks; the occurrence of hæmoptysis, its frequency or amount; attacks of laryngitis, tracheitis, or ulceration either in those situations or in the bowels, with many other contingencies, either severally or in combination, impart a marked diversity in the characters, course, and duration of this malady. In order, therefore, that these variations, with their most frequent sources and contingencies, may receive sufficient attention, I shall notice, 1st. *The more usual form of tubercular phthisis*; 2d. *The latent form of phthisis*; 3d. *The primarily acute form of phthisis*; 4th. *The consecutively acute form*; 5th. *The protracted form of phthisis*; 6th. *Of phthisis in infancy and childhood*; and, 7th. *Of phthisis in the dark races*.

16. Having considered the *forms* or *variations* of the disease as fully as my limits permit, I shall afterward take a brief view of the complications and intercurrent lesions which may appear in the course of these forms, more especially of, 1st. *Bronchial irritation and inflammation*; 2d. *Hæmoptysis in its several states*; 3d. *Inflammation, ulceration, œdema, &c., of the larynx, trachea, &c.*; 4th. *Inflammations or congestion of the lungs, or of the parts surrounding tubercular deposits, &c.*; 5th. *Inflammations of, effusion from, and adhesions of the pleura*; 6th. *Perforation of the pleura, pneumothorax, and hydro-pneumothorax*; 7th. *Diseases, especially ulceration of the intestines*; 8th. *Fistula in ano*; 9th. *Disorders of the uterine functions and organs*; 10th. *Diseases of the kidneys and urinary organs generally, and their consequences*; 11th. *Diseases of the heart and pericardium*; 12th. *Abnormal states of the blood and blood-vessels, at the commencement and at the successive stages of phthisis*.

17. i. OF THE MORE USUAL FORM OF TUBERCULAR OR PULMONARY PHTHISIS.—At its commencement phthisis may be manifest to the close observer, or it may be inferred with uncertainty, or detected with the greatest difficulty. But, as it advances, it generally becomes evident to the most careless observer. The diagnosis, however, should have reference not merely to the existence of this disease, but also to the progress it has made, as shown by the nature and combination of the symptoms and signs during its course. The division of its course, therefore, into *periods* or *stages*, according to the progress and extent of the pulmonary and associated lesions and to the nature of the symptoms, is of much importance, not only as imparting a greater precision of description, but as suggesting more appropriate indications and means of treatment.

18. A. FIRST STAGE.—a. In some cases before the respiratory functions indicate any disorder, but in others either contemporaneously with, or soon after such disorder, the habit and appearance of the body evince more or less of falling off

from the healthy condition. Cough and shortness of breathing, slight at first, and hardly observed, are early experienced. The cough is at first short, slight, occurring only in the morning when leaving the bed, consisting only of a slight hack, and afterward recurring only occasionally or more and more frequently in the course of the day, or upon exertion. It is at first dry, or attended by a slight, ropy or saliva-like fluid. The respiration, either previously, subsequently, or about the same time, is quick or hurried on the slightest exertion, and becomes more remarkably short as the cough continues or becomes frequent. At this period, or even previously to either cough or shortness of breathing being experienced, the patient's spirits, in some cases, are much depressed, and the pulse is weak and slow. This is more particularly remarked when the disease is produced or determined by exhausting or depressing causes, as masturbation or depressing mental emotions. In many cases, the pupil of the eye is much dilated, and the conjunctiva pale or pearl-like. Pallor of the countenance and a deficiency of the carnation tint of the general surface are also often observed, while the flesh is softer than natural, and somewhat emaciated. There are a general indication of languor, and a want of the elasticity of mental and bodily health.

19. These symptoms may continue for some time, without making much progress, or they may become more marked, but they are, after a longer or shorter time, according to the states of season, weather, climate, and numerous other influences, followed by greater and more general disturbance. The pulse becomes quicker than usual, especially towards evening or after meals. A chilliness, or sense of coldness, going down the spine, is experienced early in the day and again towards evening, followed by an increased heat of skin, the evening chill and heat being most complained of. The febrile paroxysm at noon may be slight, and thus overlooked, but that in the evening is attended by greater heat of skin, particularly of the palms of the hands and soles of the feet, which continues during the night, perspiration occurring towards morning. Owing to this febrile condition the patient is restless, and sleep is less sound and refreshing; cough often occurring during the night, when turning in bed, and as the disease advances. The patient readily flushes on any excitement, or after a full meal; and a tightness or oppression of the chest, or transitory pains, especially near the collar bones, are often experienced. The bowels are not much disordered, or are somewhat confined; the urine is not materially affected. The female discharges are at this stage not necessarily deranged; but they may be either excessive in quantity or frequency, or they may be scanty, difficult, or suppressed, or replaced by leucorrhœa; these disorders often accelerating, the last affection sometimes delaying, the progress of the malady.

20. Climate and weather, aided by various circumstances, very remarkably influence the progress of this stage, especially when aided by judicious treatment. With the advance of spring and summer, in this and temperate countries, the malady often appears arrested, and the general health improved. The patient sometimes gains flesh and strength; but cough and shortness of breathing seldom entirely disappear; and as autumn advances and winter returns, they become exasperated upon the slightest exposure, or even

without any known exposure, and the other symptoms also are aggravated, periods of exacerbation and of relief sometimes taking place irregularly, and tending to retard the progress of this stage, or even to carry it on to the following spring and summer, if the second stage have not previously supervened.

21. *b. This first stage of tuberculous phthisis corresponds with the first stage of tubercular development.* The lungs at this period contain a greater or less amount of tubercular deposit in what has commonly been denominated a state of crudity. The tubercles are generally of two kinds, as described in the article SCROFULA AND TUBERCLES (§ 71, *et seq.*); the one more or less firm, grayish, and somewhat transparent; the other of a pale yellowish colour and opaque. At this stage, the adjoining pulmonary tissue and bronchial membrane may not have undergone any perceptible alteration, or both may present more or less redness or vascular congestion. If *hæmoptysis* have occurred in this stage, which is very frequently the case, and which I shall notice more particularly hereafter, these changes are generally present in a more or less marked degree. The symptoms thus indicating the first stage of tuberculous phthisis chiefly are, slight cough, shortness of breathing, languor, loss of the healthy colour of the surface, commencing emaciation and flabbiness of the flesh, slight hectic fever, and the state of the eyes already mentioned.

22. *c. The physical signs in this stage are very often obscure.* This, however, depends much upon the form in which the tubercular deposit exists in the lungs—whether or no in that of isolated granules or as a continuous mass infiltrated through the parenchyma. Isolated tubercles may be so minute as almost to escape observation; or they may render portions of the lung impermeable to air, either by enlarging and approaching each other, or by the formation of more recent tubercles between them. While the solitary tubercles are separated from each other by healthy tissue, physical signs may be absent or obscure; but when portions of the lung are impermeable to air by infiltration of tubercular matter, or by the development of solitary tubercles, these signs are rendered more or less manifest, especially in proportion to the greater or less extent and rapidity of the respiratory movements. The quantity and quality of the secretions formed in the bronchial tubes have, however, great influence on the nature of the physical phenomena.

23. *d. Solitary tubercles do not, of themselves, produce the slightest change in the percussion sound of the lungs, even although they be scattered throughout the organ in considerable number.* Any change of this sound depends upon an altered state of the portions of lung between these tubercles: the sound is tympanitic when the intervening tissue has lost its contractility; but the infiltration of blood, serum, &c., into the tissue, whereby the air is expelled from it, renders the sound dull. As long as the intervening tissue continues normal the sound continues normal; but it is less sonorous, if the tissue be more dense and hypertrophied than natural. SKODA disputes the statement of Dr. STOKES that solitary tubercles, when very abundant, produce a somewhat dull percussion sound. When they do so, the intervening tissue is then most probably congested or infiltrated.

24. *e. On Auscultation the signs of solitary tu-*

*bercles* are often indefinite, owing to their number, development, and the state of the bronchial mucous membrane. The inspiratory murmur may be distinctly or loudly vesicular, or it may be indistinct or altogether inaudible, though unaccompanied by râles, or whistling, or sonorous sounds. Râles of every kind, as well as whistling and sonorous sounds, may be mixed with the vesicular or indeterminate inspiratory murmur, or râles or whistling sounds alone be heard. The expiratory murmur may be altogether inaudible, or as loud and strong as that of inspiration, and, like this, be associated with râles, and whistling, and sonorous sounds.—SKODA.

25. As the deposit of tubercular matter increases, "and in many cases even at its first deposition, swelling of the bronchial mucous membrane, accompanied or not by secretion, takes place, and then the same auscultatory signs appear as those described under the head of catarrh. The slow development of tubercles almost invariably takes place in the upper parts of the lungs, and hence, in such cases, we frequently find the auscultatory signs of catarrh permanent there, the respiratory murmur being elsewhere healthy. Rapidly developed tubercles, however, do not manifest themselves in the first instance at the apices of the lungs, but are frequently scattered equally throughout the whole of a lung, or of one lobe."\* SKODA considers that there are no distinct signs by which the existence of acute miliary tubercles can be diagnosed. Dr. STOKES states that "if in a case presenting the signs and symptoms of severe bronchitis, or in which we observe a crepitating râle continuing without intermission, we find incomplete dullness over a considerable extent of the surface of the thorax, unaccompanied with bronchial respiration; and if the stethoscope shows that the lung is almost every where permeable to air, and obstructed only at certain places, or if the crepitation be too feeble to account for the dull percussion sound, we may diagnose the acute inflammatory development of tubercle." According, however, to the experience of SKODA, most cases of acute tuberculosis are unaccompanied by any of those signs, and every one of them may be present without the disease being tubercular.

26. *f. Tubercles in Masses and tubercular Infiltration.*—a. In by far the greater number of cases of tubercular disease of the lungs, of some duration, the *percussion sound*, under one or both clavicles, is duller and emptier than natural, or is completely dull, while over the other parts of the thorax the sound is normal, or louder, or duller than ordinary. This is owing to the conglomeration of tubercles in the upper parts of the lungs, where they are slowly developed, increase in size, and, coming in contact with each other, form considerable masses. Tubercular infiltration also occurs in the form of a slow process of development in the upper parts of the lungs, and then gives rise to this change of sound under the clavicles. Generally, when the sound under the clavicles is duller than natural, it is abnormally loud in the natural regions of the thorax, the lower part of the lung being more than usually distended, owing to respiration being impeded above. Acute tubercular infiltration takes place most frequent-

ly in the upper lobes of the lungs. It produces the same percussion sound as hepatization.

[Dr. H. J. BOWDITCH, of Boston, has reported eight cases where the tubercular deposit commenced near the base of the lung and extended upward; and he estimates that these exceptional instances are liable to occur in a ratio of 1 to 150 or 200 cases. The instances observed by him were characterized by a well-marked crepitant râle behind, over the lower lobe, persisting for weeks or months, followed by the physical signs of solidification, the disease finally extending to the upper lobe, affecting both sides, and advancing to the formation of cavities, as in the ordinary form of tuberculosis. The symptomatic phenomena in these cases did not present any material variation from those usually observed in phthisis. The diagnosis involves discrimination from pneumonia. The physical signs are common to the two affections, but with this essential difference: in the tuberculous affection the crepitant râle persisted for weeks and months, solidification being slowly induced. Moreover, the history and symptoms of the case differ essentially in the two diseases. Exploration for phthisis should, therefore, not be limited to the upper part of the chest.]

27. *g. Auscultatory Signs.*—As long as the tubercular mass, or the tubercular infiltration, is of such limited extent as not to contain within it at least one large bronchial tube, it will not give rise either to bronchophony, or to bronchial breathing, or to any consonating sound. "Vesicular respiration may continue audible beneath the clavicles even when tolerably large masses of tubercles are present in the upper lobes of the lungs, provided there be sufficient healthy tissue to produce it, and the bronchial mucous membrane be not swollen nor covered by secretion. But this is not generally the case, for we almost invariably hear an indeterminate inspiratory murmur, of different degrees of strength, often, indeed, very strong, and in most cases attended by moist râles, or by hissing, whistling, and sonorous sounds; the expiratory murmur is nearly as loud, or even louder, than the inspiratory, and is likewise combined with different kinds of râles, and whistling and hissing sounds."—*Op. cit.*, p. 302.

28. If the tubercular masses or infiltration be of such extent as to embrace bronchial tubes, in which the voice or the respiratory murmur can consonate, bronchophony and bronchial breathing will be heard beneath the clavicles, provided the tubes are not filled by fluid or solid exudations, and should there be any râles, or whistling or sonorous sounds in the trachea, or in a large bronchial tube, consonating râles, or whistling or sonorous sounds, will also be heard. But if the bronchial tubes in question be obliterated, neither bronchophony, nor bronchial breathing, nor any consonating râles, will be audible, these being replaced either by indeterminate respiratory murmurs, with or without dull râles, or no murmur whatever. It is often observed, owing to the bronchial tubes being at one time filled or obstructed by mucus, and at another freed from it by coughing or expectoration, that in the course of a few minutes bronchophony is heard alternating with a dull resonance of the voice, bronchial respiration with indistinct breathing, and a clear acute with a deep dull râle, &c. Consonating and non-consonating sounds may be also heard at the same time.—SKODA.

\* *A Treatise on Auscultation and Percussion by Dr. JOSEPH SKODA; translated from the fourth Edition, by W. O. MARKHAM, M.D., p. 300.*—The best authority on Auscultation.

29. Should the tubercular masses or infiltration not be developed in the upper lobes, the respiration beneath the clavicles may be quite natural, auscultatory signs being presented over those parts of the chest which correspond with the affected portions of lung. The parts which are healthy, or which contain only solitary tubercles, yield either a weak or loud vesicular or indeterminate respiratory murmur; or every variety of râle and whistling and sonorous sounds may be audible, according as the bronchial tubes are or are not free from catarrhal affection. "There are no auscultatory signs pathognomonic of tubercular disease of the lungs; and there are none which will enable us to determine that no tubercle is present in a lung, or in any part of it."—SKODA.

30. *h.* Of the *physical signs* in this stage, it may be said that, unless there is an obvious difference between the sounds emitted in the relative situations on opposite sides, these signs are not much to be depended on; and in very many cases an opinion as to the disease has to be formed chiefly from the local and constitutional symptoms. In other cases, with the same symptoms, the physical signs afford unequivocal indications of the existence of tubercular disease. The sound elicited by percussion is evidently less clear under one clavicle, the respiration less soft and easy, and the voice decidedly more resonant than under the opposite clavicle. And, even at this early period, the motions of the upper parts of the chest during respiration may often be seen to be unequal; one side of the thorax being more fully expanded during inspiration than the other, the side least elevated being generally that which furnishes the most evident signs of the presence of tubercles. When tubercles are diffused over a large portion of the lungs, a degree of puerile respiration occasionally indicates their presence. "A marked inequality in the sound of the respiration in different parts of the chest also affords strong suspicion of tubercular disease, when such inequality cannot otherwise be accounted for."

31. *B. SECOND STAGE.*—*a.* The transition from the first to the second stage may be gradual and hardly manifest, or it may be rapid and evident. It is indicated chiefly by a change in the expectoration. The sputum, instead of being colourless, slightly grayish and frothy, either becomes muco-puriform and contains specks or streaks of blood, or presents minute specks of opaque matter, of a pale yellow colour. These specks gradually increase in number and in size, until they form curdly patches, surrounded by the transparent portion of the expectoration. The increased sputum is accompanied with more frequent, often more severe cough; the chills or sense of cold running down the spine, the evening heat of skin, the restlessness in the early part of the night, and the morning perspiration, although more severe on some days than on others, or on alternate days, become more remarkable; and hectic fever is unmistakably established. The pulse is always accelerated, more especially in the evening; the respiration quick, although the patient be at rest; and the emaciation and flabbiness of the flesh increase. Languor, debility, and an inability of bodily and mental exertion, are experienced. The face is generally pale in the morning, but it becomes flushed after a meal, and in the evening, when the fever and heat of

skin are present, the flush in the cheeks being more and more circumscribed as the disease advances. The pains sometimes complained of in the first stage are more frequently felt in this, and are referred most commonly to the vicinity of the collar-bones, or to one or both shoulders, occasionally to either side, and not infrequently to the back, or to one side of the upper half of the sternum. The pain is generally dull or aching, resembles chronic rheumatism; but it is sometimes acute, especially when it is referred to either side, and is then owing to the extension of inflammatory action, of a sub-acute or chronic form to the pleura. Before, in some cases, and more frequently after, this stage is formed, slight or more decided hæmoptysis occurs. In many instances the expectoration is merely streaked with blood, in others the blood is discharged in considerable or large quantity, and unmixed with the sputum.

32. *b.* These symptoms are occasioned by the *softening* of the tubercular matter, and by the changes in the parenchyma of the lungs and in the bronchi which attend it. The softened and diffuent matter, forming the expectoration, proceeds from the dissolution of the tubercles, from the tissues surrounding them, and from the bronchi, into which the softened tubercles open, and along which the softened matter passes, in the course of its excretion. The bronchi and tissues surrounding the tubercles, irritated by the morbid matter, furnish an increased and altered secretion, which, with the softened tubercular matter, constitute the sputum; and this varies in character with the extent and intensity of the inflammatory irritation induced by this matter in the adjoining tissues and in the bronchi. The cough depends upon, and is modified by, the amount and properties of the matters proceeding from these sources, and the degree of irritation thereby produced in the trachea and larynx. While these changes are proceeding in the earlier tubercular deposits and in the adjoining structures, the inflammatory irritation thus induced extends to the pleura, covering the portion of lung chiefly affected, and lymph is effused from it. The exuded lymph, coming in contact with the surface of the costal pleura opposite, gives rise to adhesions, which become cellular, and vary in firmness and extent with the duration and severity of the disease. These pleuritic adhesions are generally greatest over, or are confined to, the parts where the tubercular deposits are greatest; and, especially owing to the inflammatory action producing them, account in great measure for the pains experienced in the upper and lateral regions of the chest. The consequences of the softening and breaking down of the tubercles are the formation of *cavities* and various *changes* in the adjoining tissues and in the bronchial tubes. These cavities are first formed in the superior lobes, while the lower portions of the lungs are gradually becoming tubercular, the disease generally advancing downward.

33. *c.* The *cavities* may be formed by the dissolution of either solitary tubercles, or of conglomerated tubercles, or of tubercular infiltration. They are of all sizes, from the size of a pin's head to that of a large orange, or even larger. Their walls consist either of the lung-tissue infiltrated with tubercular matter, forming a more or less dense layer, and being in some cases of

such firmness as to prevent any dilatation or contraction of the cavity, or merely of a membrane or membrane-like sac, attached to the surrounding tissue of lung. In very old cavities the internal cavities often present a more or less dense, polished or smooth, and serous or sero-fibrous surface, while in others recently formed the surface varies in firmness or softness, presenting neither of the appearances just stated, in any marked form. Between these the changes of the surface are very diverse, according to the size and duration of the cavity. The cavities generally communicate with one or more of the bronchial tubes, and are rarely free from puriform mucus, or from pus, or an ichorous pus, or from blood. Owing to these differences in the size, in the walls and contents of the cavities, as well as in the surrounding structures, and to other circumstances, the physical signs which cavities present are very different and varied.

34. The extent to which the lungs have become tuberculous, as Sir J. CLARK justly remarks, varies, in this stage of phthisis, very remarkably in different cases, without a corresponding difference in the severity or duration of the symptoms. Two patients having symptoms exactly similar, may be the subjects of a very different extent of pulmonary disease. In some cases a few weeks may suffice to develop cavities of greater or less extent, while in others many months, or even years, may pass without any remarkable increase or diminution of the symptoms, or even of the pulmonary lesions. In a small proportion of cases a curative process is established, as will be noticed in the sequel (§ 145, *et seq.*), by which the tuberculous changes are arrested or partially obliterated; and if the patients' general health be maintained, the indications of tubercular deposit may gradually disappear, or at least advance no farther. But by trusting to symptoms alone, the state and progress of the tubercular lesions, without having due reference to physical signs, cannot be ascertained with any degree of precision. It must be evident, however, that a degree of importance beyond that which these signs possess should not be accorded to them, and that the fallacies to which they are liable should be duly estimated.

35. *d. Physical Signs.*—The upper parts of the chest are at this period less freely raised during inspiration than in the healthy state, and this is often more evident on one side than the other.—*a.* The sound on percussion is dull under one or both clavicles. SKODA remarks that when the cavity is formed within a portion of air-containing tissue, the percussion sound remains unchanged; and this is true not only of a small, but even of a tolerably large cavity. The only sound which cavities situated within a healthy structure yield is the cracked-pot sound, but this only in rare cases, where the cavity approaches the walls of the thorax, contains air, and is not smaller than a pleximeter. The sound in these cases is more tympanitic over the situation of the cavity than at other parts of the chest. Cavities containing air, even when deeply seated within a portion of lung infiltrated with tubercular matter, will emit a tympanitic sound if their size be not less than a walnut. Several smaller cavities, seated close together, will produce the same sound. The more flexible and movable the walls of the thorax, the more readily is the tympanitic sound emitted. The sound is clearer the

nearer the cavity is seated to the surface of the lung, and fuller the larger the cavity. The cracked-pot is most readily heard when cavities are large and superficial. "A cavity will not yield a metallic ringing sound unless it be the size of a fist, but it does not necessarily emit such a sound, though it be of that size."

36. *e. On auscultation,* a dry or large-bubbling crepitant râle is heard over large cavities, when their walls are yielding, and dilate and contract during respiration, the lung being attached to the costal pleura. This râle is most readily heard when there are several or many cavities, of the size of a pea or bean, scattered through the lobe; it is never heard alone, but in combination with other râles or whistling or sonorous sounds, owing to the presence of muco-puriform or other morbid exudations in the affected portion of lung, or its vicinity. If these latter be very loud the crepitation may not be heard. SKODA observes that when a few deep-seated cavities are present in a lung which is otherwise healthy, the vesicular breathing, interrupted by a few bubbles of a muffled râle, may be heard over them; generally, however, the murmur in such cases is not vesicular, but indeterminate. "Cavities with membranous walls, situated in the midst of air-containing tissue, even though of large size, never give rise to bronchophony, bronchial breathing, or consonating râles." These râles and whistling and sonorous sounds may take place in cavities, the walls of which have a thickness of at least several lines; and if their thickness be considerable, the breathing and the voice may be accompanied by metallic tinkling and anphoric resonance. When the walls are thick and unyielding, there is neither increase nor diminution of the size of the cavity during inspiration and expiration, the air neither entering into nor passing out of the cavity, and consequently no murmurs are emitted from the cavity; those which appear to proceed from it are *consonating murmurs*. But murmurs may be produced within the cavity, if its walls are flexible, and permit the entrance and exit of air during respiration, especially if adhesions of the pulmonary with the costal pleura exist over or near to the cavity. Râles and whistling sounds can be produced in a cavity only when the current of air is interrupted by the morbid secretion contained in it, or in the bronchial tubes communicating with it. The movement which this secretion undergoes during inspiration, and especially during coughing, is attended by râles, or by whistling sounds, when air as well as fluid is present in the cavity.

37. From the above, and owing to the varying sizes, to the situations, to the walls, to the contents, and to other circumstances, of cavities, it must be manifest that *percussion* and *auscultation* afford very few certain signs of the existence of cavities. In this opinion I am fortified by that of SKODA, the most experienced observer of physical signs in Europe. I may remark, however, that tubercular masses and tubercular infiltrations do not exist for any considerable time without producing cavities. Cavities may, therefore, be safely inferred to be present whenever the tubercular disease is of considerable standing, and when the constitutional symptoms mentioned above have existed for some time. SKODA justly remarks that "loud bronchial breathing, loud large-bubbling râles and bronchophony are often heard over cavities; but we as often, and often-

er indeed, meet with cavities which do not reveal themselves to us by auscultatory signs."

[Dr. AUSTIN FLINT, in opposition to this opinion of SKODA, that "tubercular cavities do not reveal themselves to us by auscultatory signs," remarks as follows: "As regards cavernous respiration, observations directed more especially to the variations in pitch of respiratory sounds, have led me to the conclusion, in opposition to high authority, that the ingress and egress of air, from an excavation of an adequate size, under favourable circumstances, may be readily distinguished; that the cavernous and the bronchial respiration are not, as far as audible characters are concerned, identical; and that the normal laryngo-tracheal respiration is the type of the bronchial, but not of the cavernous respiration. The distinctive features of the cavernous respiration consist of an inspiratory sound, non-vesicular, or blowing, but, compared with the bronchial inspiration, low in pitch, hollow, more slowly evolved, and of an expiratory sound, if present, lower in pitch than the sound of inspiration. A fair number of observations, in which these features of the respiration were localized during life, and found to correspond in their situation with cavities ascertained to exist after death, have led me to entertain the belief that the existence and seat of excavations may be predicated on the auscultatory characters just mentioned, whenever they are distinctly manifested. But owing to the number of circumstances which must be combined, in order that a cavernous respiration may be developed, it will often happen that when cavities have formed, examinations fail to discover the evidence of their existence. Indeed, it is often only after repeated explorations, made at different times, and conducted with much care and patience, that they are detected."—(*The Principles and Practice of Physical Exploration, as applied to the Diagnosis of Diseases of the Respiratory Organs*. By AUSTIN FLINT, M.D. Philadelphia, 1856, 8vo, p. 500.)]

38. *C. THIRD STAGE.*—This period of the disease is merely the former gradually increased in severity—the second gradually lapsing into this. But during its progress various complications, and additional phenomena, present themselves, caused by the extent of lesions in the lungs, the increase of cavities, formation of additional ones, and more extensive tubercular deposits; by the contamination of the circulating fluids, and by disease of related or remote organs.—*a.* The thorax at this stage is generally flat instead of round or prominent; the clavicles appear remarkably prominent, owing to the depression of the ribs, to a hollow space existing between them and the upper ribs, and to the shoulders being raised and brought forward. The sub-clavicular regions are nearly devoid of motion during respiration; and during a full inspiration, the upper regions of the chest seem to be raised forcibly instead of expanding with the elasticity and ease of health.

39. The constitutional symptoms are still more severe than in the former stage. The pulse becomes quicker and weaker; the hectic symptoms more pronounced; the flush in the cheeks more marked and circumscribed, particularly in the evening; the emaciation and debility greater; the cough and expectoration more frequent, especially at night and during the morning; and the breathing shorter and more oppressed. During this stage, the patient is exhausted by copi-

ous perspirations and attacks of diarrhœa, the one sometimes alternating with the other. These assume a colliquative character, and their accession at the commencement of, and continuance during this stage, have led to the denomination of *colliquative stage*, which has usually been applied to it. In addition to these, the feet and ankles often become œdematous; the nails of the fingers, if not before, are now incurvated; the cough and restlessness during night increase; copious perspirations break out as soon as the patient falls asleep; pains in the chest, collar-bones, and shoulders, or in the sides, are much complained of. The sweats and colliquative diarrhœa rapidly increase the emaciation, the integuments covering the more prominent parts of the back becoming inflamed, sore, and liable to ulceration from the pressure to which they are subjected. Nevertheless, the patient's appetite is often not materially diminished, and hopes of recovery are generally entertained nearly unto the last. With the emaciation and exhaustion, the mind becomes enfeebled, although the imagination is often active. During the last few days or weeks of existence, the mouth, tongue, or throat, or all these, become aphthous; the features sunk, collapsed, and sharp; and, in some cases, mild delirium, very rarely violent delirium, followed by sinking or coma, closes the scene.

40. The severity and rapidity of the symptoms and progress of the malady vary remarkably in different cases. In some a progressive wasting, with little pain, without much cough, but with diarrhœa and perspiration, in the last stage, is chiefly observed, sanguine hopes of recovery being entertained. In others, and these the majority, the chills and sinkings following the perspirations during the nights and mornings; the exhaustion and distress produced by the diarrhœa; the harassing cough and difficulty of expectoration; the dyspnœa and sense of suffocation; the pains in the chest, and sometimes in the bowels; the mental struggle between hope and fear, especially in the latter part of this stage, mark not only the severity of the disease, but also the distress experienced by the patient. The termination of the malady is thus characterized by a state of tranquillity, ease, and gradual sinking, in some cases, and by a painful and distressing struggle in others.

41. *b. The physical signs* are generally the same as, or more fully pronounced than in the second stage. *Percussion* generally emits a dull sound over the superior parts of the chest, although the excavations which partially occupy the upper lobes, and the emaciated state of the parietes, may render the sound less dull than in the preceding stage. On *auscultation*, the respiration is obscure in places, or even inaudible, while in others it is particularly clear, bronchial, or tracheal, or the cavernous of LAENNEC. There is a mucous râle, produced by the morbid secretion in the bronchi, and a gurgling sound on coughing; pectoriloquy is frequently distinct, although as often absent, in one or both sides, or present at one time and not at another.

42. *Pectoriloquy*, or the resonance of the voice in a cavity existing in the chest, is one of the most uncertain signs in this and the second stage, for the reasons stated above (§ 35–37). Various indeterminate sounds are also heard in different parts of the chest, often with the signs of pleuritic, pulmonary, or bronchial inflammation.

43. ii. OF CERTAIN SYMPTOMS AND SIGNS DIAGNOSTIC OF PULMONARY PHTHISIS.—The diagnosis of pulmonary phthisis is usually easy in the second and third stages, but often difficult in the first, for in this the physical signs furnish no more certain aid than the constitutional symptoms. Various aids, however, to the diagnosis have been recently recommended.—*A. Observations of the time during which the breath may be retained after a full inspiration* have been recommended (the patient being sometimes desired to count as far as he can), in the first stage of phthisis, in order to assist the diagnosis, and are of some use when carefully made; but the results vary so much in different persons in health, and still more so in other diseases of the chest, which are not strictly consumptive, as emphysema, chronic bronchitis, chronic pleurisy, and pleuritic effusions, diseases of the heart, &c., that little dependence can be placed upon them, unless when viewed in connexion with the existing phenomena and with the absence or presence of the symptoms and signs of these diseases.

44. *B. Observations by the spirometer* are in some degree liable to the same objections as those just now stated. This instrument, invented by Dr. HUTCHINSON for ascertaining the capacity of the lungs for air in diseases, may, however, be used in incipient phthisis with some advantage, but it can be employed only in public institutions. The indications of the extent to which the lungs are obstructed by tubercular deposits, must necessarily have reference to the average capacity of the lungs, of persons of the same size, in health. Consequently, it was requisite to ascertain this latter point, in the first instance; and he found, after a very great number of observations of the capacity of the lungs for air in persons in health, that this capacity increased with the height of the individual in a very determinable proportion. To this part of the subject it is unnecessary farther to refer, than to state that the "vital capacity of the lungs for air" was inferred from the average of upward of a thousand persons in health, whose lungs were thus measured. *The following table shows the comparison of healthy lungs, and of lungs in the first stage of phthisis, or before softening, all cases being males:*

No. of Cases.	Age.	Height.	Vital Capacity.		Difference.
			Healthy.	Diseased.	
		ft. in.	cu. in.	cu. in.	cu. in.
1	28	5 8	238	186	52
2	28	5 4½	206	140	66
3	37	6 2½	286	270	16
4	20	5 3½	198	120	78
5	27	5 7	230	85	145
6	45	6 0½	270	200	70
7	36	5 0½	222	182	40
8	36	5 5½	214	170	44
9	35	5 7	230	160	70
10	38	5 10½	254	140	114
11	33	5 7	230	80	150
12	28	5 7½	230	180	50
13	27	6 1½	274	260	14
14	24	5 6½	222	190	32

45. Cases Nos. 5, 10, and 11, present a great deficiency. In these both sides of the lungs were much diseased, and in the two former emphysema also existed to a considerable extent. The foregoing table, as well as the following, are taken from "*The Medical Report of the Hospital for Consumption.*" The next table shows the comparison of Healthy and Diseased cases in the second stage of Phthisis, or after softening, all being males:

No. of Cases.	Age.	Height.	Vital Capacity.		Difference.
			Healthy.	Diseased.	
		ft. in.	cu. in.	cu. in.	cu. in.
1	27	5 6	214	86	128
2	21	5 5½	214	60	154
3	45	5 9½	246	85	161
4	30	5 6½	222	70	152
5	33	5 8½	238	70	168
6	26	5 6½	222	50	172
7	28	6 0	262	70	192
8	38	5 8	238	60	178
9	41	5 9½	246	90	156
10	42	5 8	238	60	178
11	29	5 5½	214	50	164
12	32	5 7	230	70	160
13	42	6 0	270	140	130
14	29	6 2	286	150	136

46. All the cases in the above table show a very marked deficiency of vital capacity. In Nos. 3, 7, and 8, and probably in others, both lungs were extensively diseased. In the following table "*the vital capacity of phthisical patients is exhibited, indiscriminately, without reference to the stage of the disease, compared with that of the same number of healthy individuals:*"

No. of Cases observed.	Mean Vital Capacity.		Difference.	Difference per Cent.
	In Health.	In Cases of Phthisis, all Stages.		
415	cu. in. 222	cu. in. 129	cu. in. 93	cu. in. 42

47. *The following table shows the comparison of healthy individuals and of cases of phthisis in the first stage, or before softening:*

No. of Cases observed.	Mean Vital Capacity.		Difference.	Difference per Cent.
	In Health.	In Phthisis, 1st Stage.		
241	cu. in. 223	cu. in. 149	cu. in. 74	cu. in. 33

48. *Table showing the comparison of healthy persons and cases of phthisis in the stage after softening.*

No. of Cases observed.	Mean healthy Capacity.	Mean diseased Vital Capacity.	Difference.	Difference per Cent.
	cu. in. 221	cu. in. 105		
174			cu. in. 116	cu. in. 52

49. *C. Hæmoptysis* is often the first symptom which excites the alarm of the patient in phthisis, and the attention of his friends. The older writers often considered hæmoptysis a cause of phthisis, whereas modern research has shown that it is a sign of this disease, tubercular deposits being its cause. The following table, from the Report of the Hospital for Consumption, shows the *existence or non-existence of Hæmoptysis in 1381 cases of Phthisis, arranged according to the sexes, without reference to age: Males, 910; Females, 471. Total, 1381.*

	Males.	Per Cent.	Fem.	Per Cent.	Total.	Per Cent.
Hæmoptysis . . .	563	61.9	307	65.2	870	63
No hæmoptysis	347	38.1	164	34.8	511	37

50. The reporters remark that a large proportion of the above cases was seen at an early period of the disease, and that not a few of them were only a short time under observation. Hence many of those in whom this symptom had not occurred when the cases were noted would in all probability be sufferers from it during the farther progress of the malady. It may, therefore, be assumed that the proportion of cases in which hæmoptysis occurs is still greater than that shown in the table. It would result from the above that nearly an equal proportion of males and of fe-

males are found to present this symptom. The following table shows the existence or non-existence of hæmoptysis in 1084 cases of phthisis; viz., males, 706; females, 378—arranged according to the sexes in decennial periods. Also the per-centage of the cases in which hæmoptysis occurred:

Age.	Hæmoptysis occurred.		Hæmoptysis did not occur.		Total of Cases observed.		Hæmoptysis occurred per Cent.	
	M.	F.	M.	F.	M.	F.	M.	F.
0 to 5	0	3	2	4	2	7		42.9
5 to 15	7	32	14	9	21	41	33.3	78.0
15 to 25	124	107	85	45	209	152	59.3	70.4
25 to 35	175	59	71	42	246	101	71.1	58.4
35 to 45	115	35	48	25	163	60	70.6	58.3
45 to 55	29	7	23	8	52	15	55.8	46.7
55 to 65	3	0	10	2	13	2	23.1	
65 to 75	0	0	0	0	0	0		
Totals..	453	243	253	135	706	378	64.2	64.3

Dividing the age of 70 into two equal periods—into two 35 years—the per-centage of cases of phthisis in males was 64 in both periods; while in females it was 67 for the first 35 years of age, and 54.6 for the second 35 years. In females, also, from 5 to 25 years of age, hæmoptysis occurred in the ratio of 72 per cent.; while between the ages of 35 and 55 it appeared only in the ratio of 55 per cent. The reporters farther state that the stage of the disease in which hæmoptysis occurred was noticed in 696 cases, of whom 453 were males, and 243 females, as in the following table:

	Males.	Per Cent.	Females.	Per Cent.
Before softening	333	73.5	176	72.4
After softening.	120	26.5	67	27.6

This table shows that hæmoptysis is much more frequent (nearly as 3 to 1) in the first period of phthisis than in the second and third conjoined, and nearly equally so in both sexes. It is very difficult to account for this greatly increased frequency of hæmoptysis in the first stage of the disease; but it is probable that it appears greater in this stage than it actually is in practice, the whole progress of the disease having been observed; inasmuch as the reporters admit that many of the cases were only a short time under observation, and were not seen in the far-advanced progress of the malady. There can be no doubt, however, that the occurrence of hæmoptysis in so large a proportion of cases in the first stage establishes it as an important diagnostic symptom of phthisis.

51. *Hæmoptysis* is generally a symptom, but very rarely a cause, although it may determine the development, of tubercles in the lungs of a scrofulous person, or the debility induced by a very abundant hæmoptysis may have a similar effect; and, as M. ANDRAL has shown, the infiltration of a portion of the effused blood into the air-cells and pulmonary structure may form a nidus for the primary deposit of tubercles. Notwithstanding these exceptions, as far as they may be considered as such, hæmoptysis may be considered as generally produced by tubercles, although it may be conceded that, in some cases, especially when slight or moderate, it may be viewed as the result, in common with the tubercular deposit, of the sanguineous congestion of the lungs, often preceding and attending the early stage of phthisis, especially in the scrofulous and sanguineous diatheses. It should not be overlooked that the hæmoptysis may be produced by the pulmonary congestion consequent upon

impaired vital action, or upon structural lesion of the heart, and by the severity of the cough, either independently of or in connexion with these conditions of the heart, the blood effused into the pulmonary tissue and air-cells proving the matrix of tubercles, as ANDRAL contends. When hæmoptysis proceeds from these morbid states it is usually copious, and is often less dangerous than the slighter states of it, more obviously dependent upon the early stages of phthisis. BAILLOU remarked that large discharges of blood from the lungs are less dangerous than small; and although this is very frequently but not absolutely the case, it by no means deserves the importance attached to it by PORTAL. M. LOUIS remarks, respecting this symptom in this and other diseases, that, with the exception of some cases in which it depended upon external injury, or was connected with suppressed catamenia, it indicates, with a high degree of probability, the presence of tubercles in the lungs; and Sir JAMES CLARK states that his experience supports this conclusion. According to LOUIS, hæmoptysis occurred more frequently in females than in males, in the proportion of three to two—a proportion much higher than stated by other observers; and he considers it most frequent in females from forty to sixty-five, that is, after the period of the cessation of the catamenia; but in this also he is not supported by other observers in different fields of observation. The frequency of the attacks, he remarks, was generally in proportion to the duration of the disease, the more copious discharges having rarely occurred oftener than twice or thrice in the same persons. "In all his cases it was present, in a greater or less degree, in two thirds; and the numbers in which it was copious and inconsiderable were nearly equal." In some it was a frequent symptom during the whole course of the disease, in others it never appeared. In persons advanced in life and in young children it rarely occurred, and then chiefly towards the close of the disease. In rare cases it was the first symptom, even before the cough, occurring suddenly, and, as M. LOUIS asserts, in the midst of perfect health, and without any appreciable cause. This latter assertion does not agree with my experience, nor with that of Sir J. CLARK, who very justly remarks that he has generally found the aspect of the patient to have been by no means indicative of perfect health, although he may not have complained; and that he has more frequently known the hæmorrhage to succeed bodily exertion, such as running, ascending heights, or long speaking, than when no such evident cause had occurred. In these cases the hæmoptysis often does not appear until a few hours after the exertion. I entirely concur in the opinion here expressed in opposition to M. LOUIS.

52. The quantity of blood expectorated varies remarkably from a teaspoonful or tablespoonful to one or even two pints; most frequently it is only about two or three mouthfuls. In some, the blood merely appears in clots or streaks in the sputum, in others it is distinct and in some quantity; when the latter, it is generally pure, sometimes frothy or florid; at others dark or slightly clotted. Very large quantities are brought up with varying remissions; but at an advanced stage of phthisis the hæmorrhage is usually continuous, until several pints are discharged, and the patient is sunk by it or suffocated. This copious hæmoptysis is generally owing to the ero-

sion of a considerable vessel by the tubercular ulceration. It is not very often that great hæmorrhage occurs at an early period; and yet I have known cases in which upward of 100 ounces were lost at the commencement of the disease. Hæmoptysis, therefore, taking place either before or after cough or shortness of breathing, should be viewed as indicating tubercles of the lungs, although it may arise from disease of the heart, associated with the same symptoms only in very rare instances.

53. *D. Cough* is generally the earliest symptom of phthisis, but is often so slight as not to excite the attention of the patient or his relatives; and for some considerable time it may occur only or chiefly in the morning. In such cases, and at this early period, the character of the cough, the state of breathing, and the appearance of the features, particularly of the eyes, ought to be examined, and the representation, often adduced, that it is merely a stomach-cough, or from laryngeal irritation, should not receive any attention; for it may be either or both of these, and not the less depend upon, or be connected with, tubercular deposits in the lungs. The continuance of the cough for weeks, or even months, without any expectoration, is of itself sufficient to cause strong suspicions of its origin. The association of the cough with shortness of breathing, any exertion causing cough or increasing the quickness of respiration, is an additional proof of the nature of the disorder. The cough is after a time observed in the course of the day, or upon suddenly changing the apartment or the temperature, or upon reading, exerting the voice, &c., and it is afterward followed by the expectoration of a transparent frothy fluid, which is often represented as coming from the pharynx and fauces. The cough generally increases with the progress of the pulmonary lesions, but such is not always the case; for, as will be stated hereafter, it may be very slight, or almost absent throughout the disease, or appear only a few days before death. Such instances have been remarked by PORTAL, LOUIS, ANDRAL, CLARK, and myself. In the course of the chronic and more protracted cases of phthisis, even when tubercular excavations undoubtedly exist, it is not unfrequently observed that, in favourable circumstances, cough and expectoration disappear for weeks, but return upon exposure, or from errors of regimen. In the advanced progress of the malady cough is generally severe, occurs at all times, often without any evident cause, but especially at night and in the morning, disturbing sleep, occasioning pain in the chest, or even sometimes causing vomiting. In the last stage it is often followed by breathlessness amounting to a sense of suffocation in some cases, or to sinking in others. The cough at the commencement of phthisis is entirely owing to sympathetic irritation of the larynx, and not to a fluid which requires to be expectorated. As the malady proceeds, it is chiefly caused by the discharge of the morbid secretions from the bronchi, or from both the bronchi and the cavities.

54. *a. Tubercular or phthisical cough* may, however, be confounded with the *cough of catarrh*, or of *influenza*, or of *gastric, hepatic, or nervous disorders*. Of the *first* it may be said that the attack is readily referred to its cause, is well marked and preceded by the usual symptoms of catarrh, either slight or acute. It is often attended by hoarseness, by soreness of the chest or

trunk; and although at first dry and hoarse, it is soon followed and accompanied with expectoration, which is at first colourless, frothy, but afterward opaque or mucous, yellowish, or mucopuriform; both cough and expectoration generally diminishing with this change of the sputum, and shortly ceasing altogether. When, however, the catarrh assumes a chronic form, or becomes exasperated, and passes into bronchitis, the difficulty of diagnosis may be much greater. *Bronchitis*, acute or chronic, will readily be distinguished by the symptoms and signs described in the article BRONCHITIS—*Inflammation of*; and *chronic catarrh* will be readily recognized as such, although, in consequence of the state of the lungs before the catarrhal attack, it may pass into phthisis; the shortness of breathing, the increased severity of the cough in the morning, the chills in the early part of the day, the age of the patient, the appearance of the eyes, and the occurrence of hæmoptysis, evincing the transition into, or the pre-existence of, tubercular disease.

55. *b. The cough of influenza* cannot be readily confounded with the cough of phthisis, if the character of the constitutional symptoms of the former, especially the pains in the head, back, and limbs, the general malaise, and the prevailing epidemic be taken into account. Influenza, as well as measles, whooping-cough, and other epidemic diseases, when attacking persons whose lungs are prone to tubercular deposits, may determine or excite the phthisical malady, or may develop it into a very manifest, acute, and rapid form, if it had previously existed in a latent form, or in its first or least apparent stage.

56. *c. Gastric cough* is readily mistaken for the early stage of phthisis, but it is louder and harder than the latter, is more paroxysmal, and often manifestly excited by some of the more prominent symptoms of indigestion, as by flatulency, acidity in the stomach, acid or acrid eructations, by a loaded tongue which is red at the point and edges, and by various other dyspeptic phenomena, especially by disorders of the bowels and liver, and by a loaded or high-coloured state of the urine. Gastric irritation may, however, be associated with the first stage of phthisis, and, when this obtains, the diagnosis will be more difficult; but the former disorder will generally declare itself, and claim the chief attention, as the readiest and surest indication for aiding the latter affection. A *stomach-cough*, often of much severity in the morning, when a gray tenacious mucus is expectorated—the cough being severe in consequence of the difficulty of bringing up the tenacious phlegm—is not so readily mistaken for a phthisical cough, as it is generally observed in connexion with manifest signs of indigestion, and in persons of mature age or advanced in life, and of a gouty or rheumatic diathesis, or in those addicted to full living or to the enjoyments of the table.

57. *d. Hepatic cough*, owing to its dryness, or to the slight mucous expectoration attending it, may be mistaken for the first stage of phthisis. But due attention directed to the state of the hepatic functions and to the region of the liver; the pale, sallow, and sunken appearance of the countenance; the disorders referrible to the stomach and bowels, and various other sympathetic phenomena contingent upon biliary and hepatic affections, will sufficiently indicate the source of the cough, when due attention is directed to it.

58. *e. Nervous* and other *sympathetic forms* of cough are occasionally observed, especially in delicate persons; and, chiefly as occurring in these, both excite suspicions of phthisis, and require investigation. A *nervous cough* is apt to occur in females both after and before puberty, and especially as a sequela of whooping-cough or of measles, and often excites alarm, not merely as it simulates, but as it may actually complicate, the first stage of phthisis. This cough is generally paroxysmal, is severe, and in protracted attacks, being sharp, barking, or tracheal, and without, or with merely a slight watery, expectoration. In females it frequently presents a hysterical character, with indications of nervous irritability and of uterine disorder, as catamenial disturbance, leucorrhœa, pains in the loins and the lowest part of the spine or sacrum; it is often occasioned by masturbation, and not infrequently disguises, as well as complicates, the first stage of consumption. *Intestinal worms* may occasion a cough, especially in young persons, which, owing to the pallor, flaccidity of the tissues, and emaciation, as well as to the short, dry, and hacking form of the cough, may be mistaken for incipient phthisis. Attention to the abdominal functions, to the state of evacuations, and inquiries as to the symptoms of verminous disorder, will generally indicate the nature of this cough.

59. *f.* Although the *diagnosis* of phthisical cough from other forms of cough is important, yet the mere determination of this point ought not to lead us to overlook the fact that they may severally complicate phthisis, especially in its first stage, may mask this stage, and may, moreover, either excite and determine its existence, or develop it into active and manifest forms, when it had previously existed in a slow or latent state. Whether, however, these forms of cough occur independently, or as a complication of phthisis, their removal by judicious treatment is requisite, inasmuch as they are injurious to the constitution, even when existing independently, and are sources of aggravation to the pulmonary disease, when they are complicated with it.

60. *E. Shortness or Quickness of Respiration and Dyspnoea.*—Quickness of breathing is one of the earliest indications of phthisis, especially when occurring in connexion with a hacking or short cough (§ 53). It has generally a marked relation to the quickness of pulse, and the severity of the febrile symptoms; in the more latent and chronic states of the disease it is not experienced unless more or less physical exertion be used; but on ascending a height, or on other occasions of exertion, the breathing is not only quick, but is also attended by more or less dyspnoea and sense of oppression in the chest. As the malady advances, especially in its more febrile forms, and when cough and expectoration are considerable, respiration is very quick, the acceleration being much greater in proportion to that of the pulse than in health or at an early stage; and the sense of oppression and dyspnoea are also greater. These symptoms are evidently caused by the extent to which the lungs are rendered incapable of their functions—to which the capacity of the organ to receive and hold air is impaired by tubercular deposits, by condensation of portions of the pulmonary structure, and by sanguineous congestion of other parts; the occurrence of hæmoptysis, by removing the latter morbid states, often relieving the cough and the breathing for a time.

The state of the heart's action, an impaired contraction of its parietes, distention of its cavities owing to impeded circulation through the lungs, may severally also increase the pulmonary congestion, and the oppression and quickness of respiration, and favour or even occasion an attack of hæmoptysis. In many cases, quick or difficult breathing is not experienced until after an attack of hæmoptysis. In these it may be inferred that the hæmorrhage either increases the weakness of the heart's action, and favours congestion of its cavities, or infiltrates the bronchi and air-cells, or structure of the lungs, so as to impair the capacity of the organ for the reception of air; an increased frequency of respiration being consequently required to make amends for the diminution of capacity. In all cases, therefore, the state of the respiration should receive attention, and the cause of its increased frequency or its difficulty ascertained, particularly as respects the existence of lesions within or without the lungs—in the bronchi, air-cells, and pulmonary tissue, or in the cavity of the pleura, or in the heart.

61. *F. Expectoration* is not usual until the cough and acceleration of breathing, with quickness of pulse, has continued for some time. It is at first scanty, transparent, ropy or tenacious, grayish or frothy; often resembling saliva. After an indefinite period, specks of an opaque matter are seen in the transparent frothy fluid. "These specks differ in appearance, being at one time white, at another yellow, or even approaching to green, and again very frequently of an ash colour; partly sinking in water in little masses." The grayish and ropy portion of the sputum partly float in it, in the form of strim, suspending the minute tubercular masses. Before or about the time of the change of the sputum to this state, streaks, or specks, or even small clots of blood, are occasionally seen in the expectoration. As the malady proceeds, the sputum becomes more opaque, of a yellowish hue, and is coughed up with more ease and in more distinct masses. At a later period, the sputum is of an ash colour, and is brought up in distinct, rounded, flocculent-like masses, enveloped in the transparent ropy portion. If the patient be directed to expectorate in a glass vessel two thirds full of water, some of these masses will be seen to sink to the bottom; others, which are frothy, will float on the surface, and parts of these will be suspended at different depths, often retaining the minute, cheese-like, or flocculent, tubercular specks or masses, or allowing these to sink to the bottom, yet connected with the surface by the more fluid and ropy portion of the expectoration. This change of the sputum into ash-coloured, distinct masses, with more or less of a thin mucous fluid, occasionally occurs only a few days before death, but more generally it has continued for many weeks or even months before this event. In some instances it retains the yellowish, puriform appearance, and forms smooth, flat patches; and in rarer cases it is semi-transparent, tenacious, and gelatinous, and, as in bronchitis, is separated with great difficulty from any vessel containing it. "During the last days of life the expectoration is in a more dissolved state, and sometimes of a darker hue; about this period, also, and often long before, it has a very fetid odour; finally it diminishes gradually, and often disappears entirely some days previous to death."—CLARK.

62. Such are the usual appearances of the ex-

pectoration; but the periods at which it commences, and at which the changes take place, differ in different cases. Its characters also vary, or differ much, as certain complications or intercurrent affections occur in the course of the malady, as catarrhal or bronchial attacks, inflammation of the lungs or pleura, &c. The transparent, tenacious, and frothy sputum, although generally accompanying tubercular deposits, is only a secretion from the bronchi, and may take place independently of these deposits. The yellowish-green sputum, often also observed, is frequently discharged in chronic catarrh, and towards the termination of bronchitis. These, although often abundant in, and forming the chief part of, the expectoration in tubercular phthisis, proceed from the bronchial membrane. The two characters, however, which may be considered peculiar to that attending phthisis, are the striated mass, with a mixture of whitish fragments in it, and the ash-coloured, globular masses, which are observed in the more advanced stage of the disease. I agree with Sir JAMES CLARK in considering these as very rarely unaccompanied with tubercular disease.

63. The quantity of the expectoration varies remarkably in different cases, and is by no means commensurate with the extent of pulmonary lesions. It may be very small, or almost altogether absent, although large excavations are found after death; the disease having advanced rapidly to this issue. Even in an early stage, and while it is still transparent, the quantity is often very great; the disease also in these cases assuming a febrile or rapid form. PORTAL, ANDRAL, CLARK, and the author, have met with rare cases in which the expectoration has been entirely wanting, and the cough very slight up to the very close of life, and yet small tuberculous vomicae and most extensive tuberculous deposits in some cases, and large excavations in others, were found after death. The cases of this description, which occurred in my practice, had been mistaken before I saw them for low nervous or typhoid fevers, although the rapid pulse, the still more rapid breathing relatively to the quickness of the pulse, the appearance of the features, the night-sweats, the emaciation, and the appearances of the fingers and nails, might have shown the nature of the malady, independently of the physical signs. As to the sources of the expectorated matter, it must be evident that, before softening of the tubercles has occurred, and before they have communicated with the bronchi, the bronchial membrane has supplied it, in consequence of the irritation extended to this membrane from the morbid deposit, and of the congested state of the pulmonary vessels, of which the tubercular deposits and the expectoration are the common and combined results. The softened tubercles and the surfaces of the cavities consecutively formed also supply a part, often very small, of the sputa, more especially that part which is the most characteristic of the malady. In cases where the expectoration is either scanty or nearly wanting, the severity of the constitutional symptoms, the rapidity of their progress, and the indications of a contaminated state of the circulating fluids, render it extremely probable that the morbid secretion from the surface of the cavities as well as the liquefied tubercular matter, are absorbed, or imbibed by endosmosis, and carried into the blood, which it thus poisons, thereby heightening and accelerating the symptoms. From the above it may be inferred that

the state of the expectoration should always be viewed in connexion with the other phenomena of the malady; that it affords little evidence of tubercles in their early or crude stage, but when the change takes place in the sputum, and the debris of tubercles are present in it, then a very satisfactory proof is thereby furnished of the existence of the disease in an advanced stage. Besides the appearances of the sputa already considered, there are two others which deserve a special notice, viz.: *hæmoptysis*, from its frequency and importance (§ 49, *et seq.*); and *calcareous concretions*, from the various considerations suggested by them.

64. *The expectoration of calcareous concretions* from the lungs occurs either months or years after the appearance of pulmonary symptoms—generally after years have elapsed—the patient either having recovered or partially recovered, and having experienced a relapse. The size of these concretions varies from that of a hemp-seed to that of a pea or small bean. This last size is the largest I have seen, and was expectorated by a lady in the last stage of the malady, which had been of many years' duration. A medical friend was sent up the Mediterranean in 1820 for change of climate in the first stage of phthisis. He recovered, but expectorated these concretions on several occasions long afterward. He is now alive and in good health. Another medical friend lately called upon me and stated himself to have been then, and long previously, in good health, with the exception of a loud whistling noise, during both inspiration and expiration, which could be heard in any part of the apartment in which he was. He told me that he was considered to have been consumptive many years before that time. I said that he would soon expectorate one of these concretions, and he did so in a few days. It was of the shape and size of a split pea. He is in good health. But these concretions are not met with in these circumstances alone, but also in others much more serious or altogether hopeless, as in the last stage of the more chronic and protracted cases. They are then especially brought up with a copious expectoration, sometimes without any blood, at others with streaks of blood, but rarely with a more copious hæmoptysis. In a case now under my care the patient, in the third stage of phthisis, has expectorated a number of these concretions. She has been consumptive for many years; and for several years before the disease had reached this stage had occasionally brought up, with little apparent ailment, one or more of these concretions. When they appear in a state of apparent health, they are unattended by much or even any sputa beyond a little mucus, or mucus streaked with a little blood or bloody specks. The pathological conditions in which they are usually found will be noticed hereafter (§ 146).

65. *G. Pain*, especially acute pain, rarely attends the early stage of phthisis; but a slight or aching pain is often felt, although not often mentioned by the patient, in the shoulders, or near the clavicles or upper regions of the chest. In the second and third stages, pain, often of a severer character, is frequently experienced, and is generally referred to either side, or to the situation where the tubercular lesions are most advanced or extensive, and where the pleura has become implicated. When adhesions are formed between the opposite surfaces of the pleura, pains often severe are experienced, not only in one or

both sides, but also in the back or under the shoulder-blades. They are different from those of catarrh, bronchitis, and influenza, which are experienced chiefly under the sternum when coughing, and are characterized by a sense of soreness rather than by acuteness or sharpness. In some cases pain has been felt under the short ribs, and, owing to the lowness of the situation, has not always been referred to its true source. But it will generally be found to proceed from adhesions of the pulmonary, to the diaphragmatic or costal pleura. When the bowels are disordered, it may be caused by the state of the colon; but in this case the pain is not persistent, and often shifts its situation.

66. *H. The pulse* often furnishes important indications of phthisis, even before any of the phenomena already noticed can be detected. In persons about or after puberty, who are of a scrofulous diathesis, a frequent pulse, or a pulse above 80, should be viewed with suspicion, more especially if it be associated with a dilated pupil, a clear, or blue, or pearly conjunctiva, and shortness of breathing. In many chronic cases, the pulse may not be accelerated, even throughout the disease, or until its close, and may be considerably under 70 in the minute, especially in phlegmatic and bilious temperaments. A slow or natural pulse, the breathing being not much accelerated, is observed only in the more protracted cases, and when there are indications of amendment. Great quickness, smallness, or softness of pulse occurs chiefly in the more febrile or rapid cases, and in these the chances of amendment are very few.

67. *I. Hectic fever* approaches generally slowly and insidiously in phthisis, often appears in its slightest form early in the disease, and becomes more marked as the second and third stages are reached. In some cases, however, hectic is waiting, or is so slight as not to excite notice until it breaks out suddenly and severely with all the symptoms of an advanced and acute state of the malady. It is unnecessary for me to add at this place to what I have advanced upon this topic, when describing the successive stages of phthisis, and when treating especially of the several states and causes of *hectic fever*. To that article I therefore beg to refer the reader. See *FEVER, HECTIC* (§ 292, *et seq.*).

68. *K. The digestive functions* are generally more or less impaired at the commencement of phthisis, and even before pulmonary symptoms have appeared, assimilation and nutrition being also imperfect. The bowels are often not materially disordered at an early stage. They are, however, frequently more or less slow or confined, but very readily become free, or even profuse, after recourse to aperients. As the malady advances, especially as the pulse becomes frequent and hectic fever developed, the bowels are irregular in action, are sometimes costive, and afterward spontaneously and very freely relaxed, or even purged. In more chronic cases, the bowels often continue regular, and the stools are well coloured with bile, for a long time; but when the disease is far advanced, and especially towards its close, *diarrhœa* generally supervenes, and rapidly emaciates and exhausts the patient. In most cases, even early in phthisis, an active purgative, given to remove costiveness, not infrequently acts excessively; and a gentle aperient, at an advanced period, often produces the same effect,

and occasions a *diarrhœa* which it may not be easy to arrest. It is chiefly in the second and third stages that *diarrhœa* becomes severe or obstinate. M. Louis found it in one eighth of his cases from the beginning unto death; in the majority during the latter stages; in some during the last days of life only; and in four out of 112 cases it did not occur. It is often a most distressing symptom, is preceded and accompanied by severe pains, followed by great sinking and exhaustion, and is followed by rapid emaciation. The evacuations are at first yellow and bilious; but they often become watery, curdly, offensive, or emit a sour odour; the *diarrhœa* depending, as I have shown at another place, upon the state of the follicular glands and mucous surface of the bowels, produced by the morbid condition of the blood, and by the elimination of morbid or effete matters from the circulation, by the intestinal follicles, disease of these follicles and ulceration ultimately taking place (see *ARTICLE FEVER, HECTIC*, § 306). *Diarrhœa* often diminishes the cough and expectoration, but it seldom abates the morning perspirations.

69. *L. Emaciation* is generally present unless the patient is carried off, before it has advanced far, by some complication or intercurrent affection. Frequently more or less wasting may be observed early in phthisis, and in some it is the first symptom which attracts attention, especially when the disease is occasioned by vitally depressing and exhausting causes. In other cases the malady is advanced far before emaciation is considerable. This symptom is often associated with some degree of pallor and indications of deficiency of red globules, or of a thin or poor state of the blood; and this is the more remarkable, as well as the rapidity of emaciation, as the febrile symptoms and the *diarrhœa* increase. The state of the blood, even early in the disease, and the arrest of assimilation and nutrition, the consequent waste of red globules, and the impaired or deficient development of others, readily account for the emaciation, and the state of the circulation, as regards both vascular action and the vascular contents. Emaciation is an early symptom in many obscure cases, especially in persons above thirty or thirty-five years; it is not so generally observed at a very early period in young persons, especially in females, who are still regular or nearly so in their menstrual discharges. When it occurs without any manifest cause, and especially when it is attended by quickness of pulse, by morning chills, or by a sense of cold in the course of the spine, or by a short hacking cough, or by shortness or oppression of breathing, tuberculous disease of the lungs may be inferred; and if all these symptoms be present, the fuss, parade, manipulation, and charlatanism of a physical examination of the bare chest, so often unnecessarily and even injuriously practised, may in most cases be dispensed with.

70. *M. The fingers and nails* often early, but frequently also not until an advanced period, betray the existence of phthisis. The nails become uncut or bent inward upon the extremities or tips of the fingers, which are wasted; the last joints appearing enlarged or rounded, and clubbed or terminating in a coniform shape. This appearance is most remarkable when emaciation exists, and, with the symptoms just mentioned, or even alone, is a most unerring sign of tubercular phthisis.

71. *N. Œdema* of the extremities, especially of the lower, is observed chiefly or only during the last stage of phthisis. It may, however, appear earlier in delicate females, and when the catanemia are suppressed. It is sometimes so remarkable as to amount to anasarca, and, when this occurs, tubercular deposits in the structure of the kidneys, or albuminous changes in the urine, may be suspected.

72. *Morning perspirations* are among the most distressing symptoms of phthisis. The disease may be far advanced, and hectic symptoms long present, before the perspirations become copious or are complained of. When they appear, the second, if not the third stage of the malady, may be considered present; and they are then excessive, in relation to the chills and febrile reaction which precede them. This symptom is rarely absent, but it sometimes does not appear until nearly the close of life. Louis states that he has found it wanting in one tenth of his cases. When it has been wanting, I have observed the surface of the skin remarkably harsh or rough, abounding in epithelial scales, and foul or sordid. In these cases perspiration breaks out about the face and neck. It usually occurs about the same period of the disease as the diarrhœa, and depends upon the state of the blood occasioning that affection. It has been said to be vicarious of the diarrhœa, one being diminished when the other is increased; but this is not commonly the case, or in a slight degree only. The perspirations take place chiefly in the early hours of morning; if at all present early in the disease, they are only slight, or are confined to the head, neck, and chest; but when abundant, or at a far-advanced period, they break out generally over the body, and whenever the patient falls asleep. Occasional intermissions or remissions of them are observed. When they are abundant, a rapid termination of the disease may be inferred. The state of the perspiration is diagnostic of the stage rather than of the existence of phthisis; for when this symptom is manifest there can be no question of its nature.

73. *P. Aphthæ* are common in the last days of phthisical existence, during a week or two before death. They are sometimes slight, and in others severe. They may extend over the mouth, fauces, and pharynx, rendering deglutition difficult, painful, or even nearly impossible. When severe, the patient rarely lives many days; and yet, in two cases of chronic or protracted phthisis under my care, the patients rallied, and lived two years in the one case, and three in the other, after aphthæ were present for a considerable time in a severe form.

74. *Q. The hair* falls out in the advanced stages of the febrile or acute cases, and becomes more and more thin, and, in the mornings, wet with perspiration. But in the chronic and protracted states of the disease, it generally continues abundant, or in its usual state, nearly to the last, or until a short period before death. It often falls out very early when the malady has been caused by masturbation or premature or excessive sexual excitement.

75. There are various other contingent phenomena which sometimes supervene in the course of phthisis. Some of these either accompany certain forms of this disease, or result from complications which will be noticed in the sequel. Irritability of temper, nervous susceptibility, tre-

mors, sinkings, &c., are often observed in the course of the malady, are consequences of the exhaustion of organic nervous power, and the consequent impairment of assimilation and nutrition, and the waste of the tissues and blood-globules. Nevertheless, the appetite of the patient, although fastidious and various, is generally not remarkably impaired. In the more chronic cases it is often natural, or but little diminished, until the last days of life. The mental powers are not materially affected. The reasoning faculties and the imagination are even unusually acute. In some cases, of the febrile form especially, slight or mild delirium occurs towards the close, but it is seldom violent unless the membranes of the brain become the seat of increased vascular action, with or without tubercular deposits, or the treatment is injudicious.

76. *iii. OF CERTAIN FORMS OR MODIFICATIONS OF PHTHISIS.*—The more usual form of phthisis having been described, with due reference to its stages and prominent symptoms, and to those physical signs which indicate the commencement and progress of the malady, in as far as they are entitled to confidence, or deserve to be made the basis of diagnosis, I proceed to notice briefly the more marked forms which the disease may assume under the influence of constitution, diathesis, predisposition, and causes. On this part of my subject much may be advanced, both as topics of speculation, and as matters of important practical interest; much, also, may be remarked requiring farther elucidation and more accurate investigation. Where the data are not positive, doubts may lead to more patient research, and to more positive knowledge.

77. *A. THE LATENT FORM OF PHTHISIS.*—This form is always insidious in its accession and progress. The patient is debilitated, indolent, mentally and physically depressed, and often complains of general malaise. The health is impaired, and lowness of spirits experienced. Emaciation is slight, and advances slowly. This state may continue some months or even years, and may be viewed as owing to nervous debility, or as approaching to hypochondriasis. The digestive, assimilating, and nutritive powers are more or less manifestly impaired; the surface is pallid and cool; the conjunctiva of a pearly hue, and the pupils usually dilated. The pulse is at first slightly or not at all accelerated, or quick or small; but becomes rapid on slight excitement, when also the breathing is short. Slight chills are afterward felt, or a sense of cold in the course of the spine, followed by heat of the palms of the hands or soles of the feet, and an increase of pulse. A short or slight hack or dry cough is observed, especially in the morning, or after exertion, when the breathing becomes short or oppressed. These symptoms are commonly but little attended to by the patient, although they often excite the anxiety of those about him. Aching pains are also sometimes experienced about the clavicles and upper regions of the thorax, but these, also, often fail to excite attention, or are viewed as rheumatic. Upon examination, a slight dulness on percussion, a feebleness of respiration, and a slight tracheal character of the vesicular murmur, or a louder or longer expiratory sound, are the chief physical signs.

78. Latent phthisis may occur in all temperaments, especially in the lymphatic, nervous, and bilious, and at all ages, and not infrequently in

the aged. In younger persons these symptoms sometimes disappear after change of climate and judicious treatment, or they increase and are followed by the grayish expectoration attending the first stage (§ 18); but generally, after many months, or even some years, the disease passes into one of the more declared forms about to be noticed; or the patient, having either partially or altogether recovered, expectorates the calcareous concretions noticed above (§ 64), often with little cough and scanty sputa; the expectoration of these sometimes occurring at intervals, or ceasing permanently, recovery being complete. Most frequently, however, after exposure, or after difficult, scanty, or suppressed catamenia, or after a severe catarrh, bronchitis, or limited pneumonia, or after influenza, measles, fevers, whooping-cough, &c., and even without any manifest cause of exacerbation, the disease passes into a chronic or a protracted, but open and manifest phthisis, or into a consecutively acute form, with the usual expectoration, perspiration, diarrhoea, emaciation, &c., and with the physical signs attending the far-advanced states of the malady. Hæmoptysis is not frequent in this form unless in its latter stages. The disease may continue latent in females, often masked by other ailments, as hysteria, chlorosis, uterine disorders, dyspepsia, bronchitis, or by pregnancy, until, upon the disappearance of the catamenia, or after parturition, or suckling, it breaks out into an open and acute form, and terminates rapidly, generally with fever, and sometimes with delirium.

79. This form of phthisis sometimes follows depressing or exhausting causes, or prolonged or neglected dyspepsia and impaired assimilation and nutrition, or catarrhal or bronchial affections, or hysteria, or pneumonia, or pleurisy, or affections of the throat, or partial anæmia; and these or other contingent or intercurrent disorders may mask its early course, in both sexes and at all ages, until it assumes one or other of the manifest forms about to be noticed. It is frequently connected in its origin and progress with a poor state of the blood, or deficiency of the red globules; this state of the blood, in connexion with impaired organic nervous power, either occasioning or developing the tubercular deposits.

80. The lesions most commonly seen in the lungs in this form are cicatrices in the upper lobes, with or without calcareous formations in or near their centres; crude and softened tubercles; both old and recent cavities, the former being somewhat contracted and having their surfaces smooth, or presenting a fibro-serous appearance, and adhesions both old and recent between the opposite surfaces of the pleura in one or several places.

81. *B. PRIMARY ACUTE OR RAPID PHTHISIS.*—This form occurs in persons apparently in good health, breaks out suddenly, and runs its course rapidly—in from five or six weeks to three months—owing either to the extent and severity of the morbid action, or to the feeble powers and defective vital resistance of the patient's constitution. This state of the disease occurs chiefly in young persons, and is often developed by measles, fever, scarlet fever, influenza, catarrh, bronchitis, pneumonia, or whooping-cough; and, although symptoms of tubercular disease were not evident before it supervened upon these maladies, or otherwise rapidly broke out, it may be inferred that it had previously existed for some time in a latent state, and that, when it had reached a certain ex-

tent, the symptoms and signs of its presence became rapidly manifest. In some cases severe physical exertion, fast running, loud speaking, has determined an attack, with more or less hæmoptysis and all the more violent and unfavourable symptoms of the malady. In these cases, the diseases just mentioned and other efficient causes have called the latent tubercular deposits into activity, not merely developing and accelerating their progressive changes, but also exciting morbid actions in the structures surrounding or adjoining them. That this view is correct is shown by the occurrence of this form chiefly in the serofulous, lymphatic, and inflammatory diatheses, and in members of a family in which others have been subjects either of external scrofula or of phthisis. That the diseases just mentioned, or attacks of pulmonary congestion, or other causes, should have so rapidly given rise to tubercular deposits as the history of this form may indicate, is not very probable. It is most likely that the tubercles, at an early and latent state of their formation, had existed previously to operation of these causes, and had been thereby developed into a rapid maturity.

82. This form of phthisis may be divided into *two varieties*; viz., that in which the more characteristic phenomena of phthisis are present in a remarkable and severe degree, and that in which these phenomena are nearly if not altogether absent, the disease being often mistaken for low nervous or typhoid fever.—*a.* In the former of these the patient is attacked by chills, quickness of pulse, oppressed and rapid breathing, an aching pain and anxiety in the chest and præcordia, the pain or aching extending to the spine and shoulder-blades; a short cough, which is afterward constant and severe, with a scanty and frothy expectoration at first, which soon becomes copious and yellowish; and acute hectic fever, the pulse being very rapid and soft, the remissions slight, and the perspirations excessive and almost continued. The sputum now is generally similar to that ushering in the second stage of the more common form (§ 31). The countenance is anxious, pale, covered with perspiration, the conjunctivæ clear, and the pupils dilated; the surface of the skin has a pallid or dirty hue, the tongue is dark or loaded, and the prolabia somewhat livid; the cough, oppression, and dyspnoea are so distressing as often to prevent the patient from lying down, and the breathing is short, shallow, and rapid. Hæmoptysis to a moderate extent sometimes occurs, but rarely produces relief. Vomiting takes place in rare cases. Diarrhoea occasionally appears towards the close, but is seldom severe, yet emaciation is considerable. At last the pulse can hardly be counted, and the dyspnoea is most distressing, and the cough almost suffocating. Slight delirium supervenes, the fingers and lips become livid, the nails dark and uncut, and death ensues, from four to seven or eight weeks from the attack, preceded for a few hours either by coma or indications of impending asphyxia. On percussion a dull sound is heard over nearly all the chest. Respiration is very weak in some places, and bronchial in others, and a mucous râle is generally present. No crepitation is heard, nor is the sputum characteristic of pneumonia. It is usually yellowish, is sometimes streaked with blood, or contains small clots of blood.

83. This form of the disease generally occurs

in young persons. I have seen it most frequently in females, especially after measles, influenza, and hooping-cough, and the suppression of the catamenia. In these the attack has often been produced by exposure to cold; and in some cases to which I have been called the disease has been considered either as bronchitis, or as pneumonia of both lungs, both which it nearly resembles. Indeed, it may be said to be very nearly allied to congestive bronchitis on the one hand, and congestive or nervous pneumonia on the other; but the previous history of the case, the scrofulous diathesis, the effects of treatment, the remarkable rapidity of breathing, the character of the sputa and of the physical signs, indicate the difference, as well as the alliance, between these diseases, and the appearances after death fully confirm this relation (§ 132). In 1853, a case of this kind occurred in a near relative; and in 1854 I was called to a recently married couple, both under twenty-five years, both of the scrofulous diathesis, and viewed by the father of one of them, himself a physician, as possessing a strong tendency to phthisis. Both were attacked with measles a few weeks after their marriage, and on recovery they went to the sea-side. They resided there for a short time, and, on returning to town, were exposed to cold. The lady had had the catamenia in excess; but she had passed the usual period two or three weeks, without indications of pregnancy. Soon after her exposure she was suddenly seized by chills, oppressed breathing, cough, and the other symptoms just mentioned. The attack was viewed as congestion of both lungs. External derivatives, a moderate cupping over the sternum, followed by dry-cupping in this situation and between the shoulders, and the treatment described hereafter, were prescribed. The disease proceeded as above, and terminated fatally in about five weeks. Her husband was seized in nearly a similar manner, but not so severely, very soon after her death. During her illness he appeared pallid, depressed mentally and physically, and slightly anæmised; his pulse was very rapid and weak. He had soon afterward a very slight, short cough in the morning, no expectoration, but hurried breathing on slight exertion. He did not wish to be considered ill, and refused medicine. Immediately after his wife's funeral, and more than usual exposure, he was seized with the acute symptoms mentioned above, and in a few weeks these terminated fatally, with slight delirium and coma.

84. *b. The lesions in this form of phthisis have been considered by ANDRAL as those of a form of pneumonia, attacking the scrofulous diathesis, the gray tubercular granulations found after death being regarded by him as the results of inflammation of the air-cells. But the crude and more advanced tubercles formed in addition to these granulations, the quantity of tubercular matter infiltrating and consolidating portions of the lungs, the more general extension of these lesions throughout the lungs or to the lower lobes, the indications of vascular congestion of the pulmonary structures, and even of the bronchi, and the presence of some degree of œdema or serous infiltration of these structures; and still more the occasional existence of small recent cavities, partially evacuated of their contents, and without lining membranes, are evidences that the tubercular deposits, from their extent, and the sudden production of congestion of the pulmonic and*

bronchial tissues, had developed, more or less rapidly, a state of vascular action in these tissues, of an asthenic character, that had reacted on the tubercular deposits, and had accelerated their development; the severity and rapid fatality of the disease being occasioned by the great extent of these deposits, and by the associated changes in the lungs.

[The diagnosis of this form of *acute* phthisis is somewhat difficult, the physical signs being less distinctive than in ordinary tuberculosis. A marked disparity in the percussion-resonance is not always apparent, owing to both lungs being simultaneously, and in some cases about equally affected. This affection is characterized by an abundant and extensive deposit of gray, semi-transparent granulations, often in the form of infiltration, which undergoes a rapid process of softening, leaving corresponding excavations, if the patient survives a sufficient length of time. Notable dulness on percussion may not be manifest, if the granulations remain isolated. Auscultation may not furnish morbid phenomena other than are afforded in acute bronchitis, viz., the vibrating and bubbling sounds, including the sub-crepitant râle. The vocal signs of tuberculous solidification, viz., exaggerated resonance, broncophony and fremitus, are wanting. The prominent symptoms are chills, followed by febrile movement, rapid pulse, heat and dryness of skin, great debility, hurried respiration, dispnoea, lividity of the prolabia, cough, more or less violent, dry, or accompanied by little expectoration, which is sometimes bloody, &c. Emaciation is generally much less strongly marked than in ordinary tuberculosis. Reasoning by exclusion, we shall, with due care, be able to distinguish this form of disease from cardiac affections, pneumonitis, bronchitis, or typhoid fever, with which it has sometimes been confounded.]

85. *c. The second variety of acute phthisis closely simulates either nervous, remittent, or typhoid fever, according to the modifications it presents in individual cases, while the first variety closely resembles congestive or nervous pneumonia (see LUNGS, INFLAMMATIONS OF, § 62, et seq.), in some respects, and asthenic bronchitis of both lungs in others (see BRONCHI, &c., § 37, et seq.).—This variety of acute phthisis is rarer than the preceding, and has not been noticed by those who have adopted diseases of the lungs for their speciality, the examination of the bared chest for the grand coup of fussy diagnosis, and the stethoscope as the baton of transcendental medical knowledge, if not of actual inspiration. This neglect is most extraordinary on the part of those who usually consider every case which comes under their view as pertaining to that region of medical science which they suppose themselves to be alone capable of cultivating. As in the preceding variety, so in this, the patient has appeared in good health, and if he have not felt this to have been the case he has not admitted it; nor have his friends detected it until he is seized by an outbreak of disorders which obliges him to keep to his bed and have recourse to medical aid. If this aid be of a proper kind, it will be found and admitted, at least in some cases, that a degree of ailment had been experienced for a considerable time before the accession of acute disease; that depression of spirits, indolence or indisposition to mental and physical exertion, debility, loss of appetite or indigestion, acceleration of breathing when ascending a*

height, weakness in the joints, occasional chilliness, followed by heat in the palms of the hands or soles of the feet, especially at night, some degree of restlessness in the early part of the night, loss of colour or complexion, in some cases loss of flesh, an unusual brightness of the eyes, &c., had been present for some time, but that each or all of these were so slight as not to excite the anxiety of the patient, or they were not so manifest as to rouse the fears of his friends. The patient now feels a general prostration, has a quick pulse, with the usual symptoms of a remittent form of fever, which in a few days assumes a more continued type, the symptoms being, however, somewhat severer on alternate days. The bowels become irregular, at first confined, and afterward inordinately relaxed; the perspirations are usually abundant; the tongue is foul or loaded; the urine rather scanty and high-coloured, with copious deposits; the position in bed is on the back, with the head and shoulders more or less raised, or partially turned to either side; the features are somewhat sunk, the face pallid, and the general surface dusky, with a clammy perspiration, which is abundant over the head, face, neck, and chest; and aching or dull pains are occasionally felt about the clavicles, in the back, and under the scapulæ. During the course of these symptoms little or no cough is observed; if it be present it is commonly slight, dry, and insufficient to attract attention; but the breathing is remarkably quick, somewhat oppressed, and shallow. There is little or no expectoration, the sputum and other local symptoms being insufficient to direct attention to the state of the lungs, or to excite suspicions of the existence of rapid febrile phthisis, both cough and expectoration being apparently absent. The pulse is more and more rapid, slight or wandering delirium occurs, especially when the patient dozes or falls into a waking sleep; the hair becomes thin; the surface more dusky; the emaciation very rapid and extreme; and bed sores readily form on the more prominent parts. Death soon ensues, generally in four or five weeks from the commencement of the acute attack, either from the exhaustion consequent on diarrhœa, or from coma, or sinking following delirium.

86. *d. Lesions.*—I have seen four cases of this variety of febrile consumption, to which I was called in consultation at an advanced period of their course; and at that time the symptoms and signs of phthisis, in its third stage, were more or less manifest, upon a careful and minute examination, and with due reference to the history of the case and to the health of other members of the family. In three of these an *inspection after death* was allowed, and in all several cavities were found in both lungs mostly altogether empty and nearly dry. The blood in the lungs was of a dark colour, and only partially coagulated; few or no adhesions were found between the opposite surfaces of the pleura; and the lower lobes were as much diseased as the upper. The intestinal follicular glands, both solitary and aggregated, were more or less enlarged and ulcerated. Three of these cases occurred in females. The youngest was 18 years of age, the oldest of all was 27 years. It may be inferred that the cavities, which were small, mostly empty, and the smallest only, in two or three instances, full of these usual tubercular and fluid matters, had not communicated with the bronchi, or that the bronchi in

connexion with them had been rendered impervious in the parietes of the cavities, from the condensation of the surrounding tissues, and that the morbid matters in these cavities had become absorbed, had contaminated the blood, and occasioned acute febrile symptoms of a typhoid or adynamic character. The circumstance of the softened tubercular matters in the cavities, and the morbid fluids flowing into them from their ulcerating parietes, not having passed into the brouchi, accounts for the absence not only of expectoration, but also of cough; while the emptiness of the excavations shows that their contents must have been absorbed, and being carried into the blood, explains the acuteness, the rapidity, and the typhoid character of the attendant fever.

87. *C. CONSECUTIVELY ACUTE PHTHISIS* is different from the two preceding varieties, chiefly as regards the character and duration of the symptoms preceding the exacerbation of the disease, and the development of the more acute and dangerous form. In these varieties the patient seems in tolerable health to those about him, and believes himself to be so, until the acute symptoms make their appearance, although the experienced observer cannot fail to remark indications of the approaching evil.—*a.* But the variety now about to be noticed is preceded by a slower and more manifest disorder of the respiratory functions than that preceding these varieties, and is in every way similar to the *latent* form of the malady, described above (§ 77, *et seq.*), although by no means latent to any attentive observer. After pallor of the countenance, or slight indications of anæmia, with or without emaciation, debility and inactivity, mental depression, languid or soft pulse, shortness of breathing, or short cough on exertion, and sometimes after the expectoration of calcareous concretions, have continued for a very considerable or even a long time, or for several months, or even years; and generally soon after exposure to cold, or after unusual exertion, the patient experiences chills or shiverings, or a sense of cold running down the back; or he is seized with hæmoptysis, and all the acute symptoms are fully evolved. Hectic fever, at first remittent, but afterward nearly continued; a rapid, weak pulse; very quick respiration; cough and copious expectoration; pains about the clavicles, scapulæ, or the sides, or the upper regions of the chest; colligative perspirations, diarrhœa, rapid emaciation, aphthæ, sometimes with, but oftener without, slight delirium, ultimately supervene, and terminate life.

88. *b. The lesions* most frequently observed after death in this variety are, tubercles in various states of softening; small, or nearly cicatrized, or contracted cavities, with gritty, calcareous, or cheese-like matters in or near their centres; larger cavities, partially empty or containing blood, if hæmoptysis had preceded dissolution, and their parietes varying in appearance with their duration; condensation of the pulmonary tissue around the excavations, or congestion of portions of the lungs, and redness of the bronchial mucous membrane, &c.

89. *D. PROTRACTED PHTHISIS* may commence either in the usual form, or continue for years, first in a more or less latent, and afterward in a manifest state. It occurs chiefly in the phlegmatic and bilious temperaments. It is often characterized by slowness of the pulse, which seldom rises above 70, and often not above 65 in a min-

ute, by attacks of hæmoptysis, or more rarely by the expectoration of calcareous concretions; but, when the latter occurs, I have very seldom observed the former, unless in a very slight degree. It is sometimes simple or uncomplicated, but it is oftener associated in various periods of its course with one or other of the affections and lesions about to be mentioned. The nature of the disease is generally manifest; and the experienced observer will rarely fail to form a correct diagnosis, even without the aid of a physical examination, between it and bronchitis or chronic pneumonia, with either or both of which, however, it is often associated, at different periods, and even also with partial pleuritis. Percussion and auscultation are of use chiefly as showing the progressive changes and complications of the disease, although they are liable to the fallacies noticed above (§ 35-37), owing mainly to the states of the cavities, when they exist, and of the bronchi, arising from the presence or absence of the morbid matters that usually collect in them.

90. Several cases of very protracted phthisis have come under my notice, several of them in medical men. Dr. T. was attacked by hæmoptysis at the age of 20, when studying in Edinburgh. His circumstances having admitted of his relinquishing practice soon after entering upon it, and having experienced returns of the hæmorrhage with other pectoral symptoms, he travelled or voyaged to several parts in the West Indies, and in the south of Europe, generally passing a part of the year in one or other of these, and returning to England in the summer. Nevertheless, his phthisical symptoms never left him, were exacerbated after considerable intervals, and the hæmoptysis also returned, and was sometimes alarming. This state of health continued for many years, and he continued to pass his winters in some mild climate, most frequently in that which he found to agree the best with him. At about the age of 57 or 58 he first called upon me, told me his case, and informed me that he had consulted all the consumption doctors, and that they were almost equally divided as to the existence or non-existence of cavities. I told him, after a careful examination, that there were cavities in both lungs, but that they were small, and that they most probably were filled up by the accumulated morbid secretions for a considerable time, and thus they escaped detection. He continued under my care for several years, during the periods of his residence in London or its vicinity. But the attacks of hæmoptysis were more frequent, so much so ultimately that he always carried with him pills consisting of the ergot of rye, and a bottle of turpentine. He took the former as soon as the hæmorrhage appeared, and if that failed, he had recourse, as I had directed, to the turpentine. These means generally succeeded, but the other pulmonary symptoms gradually advanced. When about the age of 67, he was seized with hæmoptysis when getting out of a railway-carriage at Paddington, had recourse to his usual remedies, and sent for me.

91. Before I reached his residence he was dead, suffocated by the hæmorrhage. The body was inspected the following day. Several cavities were found in both lungs. None of them were large. The smaller were apparently contracted; their parietes were smooth, fibro-serous, and almost fibro-cartilaginous in parts; and one or two of them so much reduced as to be almost cicatrized;

the parietes being quite smooth and fibro-cartilaginous. The surrounding tissue was condensed. Some of the cavities had membranous parietes, while in others the walls consisted of a somewhat condensed pulmonic tissue, with minute openings, chiefly venous or bronchial. The cavities were all filled with blood, as were also the larger bronchi, and contained but little mucopuriform matter. This case had evidently been of forty-four years' duration; and it presented appearances, as respected the cavities, of the longest and shortest duration.\*

92. *E. PHTHISIS IN INFANTS AND CHILDREN* occurs chiefly in the scrofulous diathesis, or as a consequence of protracted or neglected disorder of the digestive and assimilating functions, which in children may generate both the scrofulous diathesis and tubercular disease. Disorder of these functions may in all temperaments so affect the circulating fluids as to develop that habit of body, in early life, which constitutes the scrofulous diathesis, and which, in its more manifest states, implicates not merely the lungs, but other organs

\* Dr. W. H., who had been editor of the "London Medical and Physical Journal" in the years 1819, 1820, and 1821, in 1823 evinced indications of pulmonary disease, and in the following year he had a most severe attack of hæmoptysis. He came under my care, and I advised him to pass the following winter at Naples. He returned to England in June, but was more or less of an invalid all the summer and autumn. He went to the coast of Devonshire the next winter; and he thus continued to change his place of residence for many years, often returning to London or its vicinity during portions of the summer and autumn. The pulmonary symptoms were sometimes slight, at other times severe. He died about 25 years after his first attack, in the vicinity of London. The treatment of this case, and of Dr. T.'s, was conformable with that which I shall have to recommend in the sequel.

Miss L. came under my care about nine years ago, in the third stage of phthisis. The symptoms and signs of cavities in the lungs had previously been recognised by the physicians whom she had previously consulted. When I saw her these were unmistakable. During the years which have intervened since my first visit, she has experienced intercurrent attacks of bronchitis, of partial pleuritis, &c., which have been successively overcome; and during the severe winter and spring of 1855 she was not confined a day to her apartment, and but rarely to the house. The physical signs and chief symptoms of cavities in the lungs still exist. I could adduce numerous other instances of the protracted form of this disease, if it were necessary to do so.

[We have known many cases of very protracted phthisis where the individuals lived to a good old age, and were capable of performing a considerable amount of labour during their long lives. Dr. W. was a well-known practitioner of New York, who died at the age of 68, and who in early life laboured under all the symptoms of pulmonary tuberculosis. After death extensive cicatrizations were discovered, showing the former existence of cavities. Dr. K., surgeon U. S. army, also laboured under tuberculosis for more than thirty years, during most of which time he was engaged in active service, and enjoyed a comfortable state of health. In both of the above cases hæmoptysis was a frequent occurrence.]

Dr. C., of Utica, is another instance of the same kind, where all the physical signs of tuberculosis of the lungs, inducing cavities, have existed for more than 20 years, and yet he has been able to teach and practise his profession as extensively and successfully as almost any member of it. I could extend this list to more than twenty, which have come within my own observation; but a history of them would only go to confirm what is already well known, viz., the very protracted nature of this disease in particular exceptional cases.

More than 20 years since we attended a female who had laboured under amenorrhœa for more than six years. During the last year, she had a regular monthly attack of hæmoptysis, which lasted two or three days, the amount of blood expectorated being about the same as in an ordinary menstruation. She then married happily, has had several children, has never since experienced any symptoms of pulmonary disease, and is now (Jan., 1856) in the enjoyment of good health.—*Am. Ed.*]

also. When treating of *Scrofula* and *Tubercles*, I have shown that the scrofulous diathesis may either be inherited or generated by the parent, and by the offspring in childhood, by causes which depress or exhaust organic nervous power—impaired digestion and assimilation of the hæmatosine, and imperfect nutrition resulting therefrom—and thus engrafting scrofula and tuberculosis upon any temperament. It is therefore most important that this disorder of the digestive and assimilating functions in childhood should be recognised and traced to its causes, and that these causes should be removed.

93. The aspect of children thus affected suggests the idea of imperfect organic power. The child is languid or fretful; the flesh is flaccid; the skin harsh, dry, and unhealthy to the sight and touch. It is disinclined to play or to active exercise. The face is pale, pasty, or faded. The eyes appear large; the pupils are dilated, and the conjunctivæ white. The tongue is whitish, and dotted with small red points, the extremity and sides being red, and the root and centre loaded, or more or less furred, especially in the morning. The appetite is variable, often craving or unnatural; thirst is not infrequent, and the breath is fetid. The bowels are irregular, most frequently costive, but sometimes very loose; and the evacuations are offensive, often pale, grayish or clayey; occasionally mucus and imperfectly digested food are observed in the stools. The urine is either high-coloured at times, scanty or abundant, turbid or pale. The extremities are usually cold; and sleep is disturbed, and often followed by partial night-sweats. The child often talks when asleep, or grinds its teeth; and hence the complaint is often ascribed to intestinal worms, with which, however, it is not infrequently complicated.

94. If the complaint continue, the symptoms are not only increased, but others are superadded. The countenance is more faded and pasty; the upper lip is thick, tumid, or fissured; the throat and fauces red or sore, or the tonsils enlarged; the eyelids and tarsi are inflamed, or the pupils are dilated, the conjunctivæ pale or pearly; the nostrils are somewhat swollen or sore, or discharge a thick mucus; and mucus, mixed occasionally with blood, is passed from the bowels with frequent offensive and griping motions. These symptoms may continue for some time, the flabbiness and emaciation increasing, and becoming associated with quick respiration, cough, and mucous expectoration, occasionally streaked with a little blood. The skin is harsh and dry, but sweats break out during the night; languor and debility increase; the pulse and respiration are greatly accelerated; and the quickness of the latter relatively to the former increased. The pulmonic symptoms become, in most cases, more manifest, but vary much with the age and temperament, or habit of body, of the child. In the very young, they are often marked by disorder of the bowels, which frequently appears urgent, and is more or less connected with tubercular deposits in the mesenteric glands. In others, the great size of the head and the emaciated state of the limbs lead to the suspicion of incipient disease of the brain or its membranes, which indeed may be actually commencing, either as softening of the central parts of the organ, or as tubercular formations in the membranes; but these changes, as well as those in the mesenteric glands, may be

contemporaneous with tubercular deposits in the lungs also, the amount of disease in this organ either predominating or advancing *pari passu* with that in the others. In many, especially the very young, the pulmonary tubercles never reach the stage of dissolution and tubercular vomica, the disease of the brain, or of the mesenteric glands and bowels, or the extent of tubercular infiltration of the lungs, even of the lower as well as of the upper lobes, terminating life before this stage is approached or advanced, although the emaciation, and the oppression and acceleration of breathing, are extreme.

95. In these cases the cough and expectoration may be slight; but the dulness on *percussion*, and impaired motion of the ribs, are generally remarkable. The other *physical signs* are nearly the same as stated above in respect of the early stage of phthisis (§ 24, *et seq.*); but those of percussion are more to be depended on than of auscultation, especially in young children; and, in those particularly, hæmoptysis rarely occurs, unless at an early period, and then as merely streaking the expectoration; but slight epistaxis is sometimes observed. The younger, also, the child, the more general are the tubercular deposits in the several organs, especially in the lungs, in the bronchial glands, in the mesenteric glands, membranes of the brain, &c.

96. *F. THE DARK RACES* are much more exempt from phthisis than the white; but very much depends upon race, and upon continued residence in the same or similar climate, on the one hand, and migration to a colder climate, on the other.\* Of the degree of prevalence of this malady in different races, some notice, although insufficient, will be taken in the sequel; and I can here only mention the much greater prevalence of this malady in these races, especially the negro race, when they migrate to a temperate, or a cold or changeable climate. As to the usual course of the disease, when it attacks individuals of either a black, brown, or copper-coloured race, I am not enabled to speak with confidence; but, from what I have seen, it commences silently and insidiously, and advances more and more openly and rapidly to its fatal issue. In some cases the attack appears as a vital blight, by which the lungs are especially affected; a lower range of temperature or greater exposure than heretofore experienced, or other depressing or exhausting causes, while they impair organic nervous power, and the assimilating functions, thereby develop tubercular deposits in the lungs, as the parts most predisposed, by structure and exposure, to experience this morbid change, generally without any inflammatory precursors or complications. These races, as far as I have had occasion to observe, rarely or never present the protracted and very chronic states of the malady sometimes seen in the white races; while the more rapid or acute forms are frequently met with, but these generally with fewer indications of febrile or excited vascular action than in the white races. Hæmoptysis is, I believe, less frequently observed as a symptom or complication of the disease in the negro than in the latter races, while it is a severe and frequent symptom in the mixed races of South America.†

\* [Of the blacks who escape from the Southern States to Canada, a large number perish within the first five years from tubercular and scrofulous affections.]

† Dr. ARCHIBALD SMITH, in a very interesting account

## 97. IV. THE STATES OF THE BLOOD IN PHTHI-

*of the Diseases of Peru*, states that "in Spring, a season when many severe cases of pneumonia present themselves, the commonest catarrh generally appears under a more febrile form, and when it unfortunately affects one of a consumptive tendency, it is frequently the exciting cause of a galloping decay. For at this season it is remarked that consumptive patients, with which the hospitals in Lima are well supplied, die very speedily, while at other seasons they linger on for a longer period. Persons who are habitually subject to chronic *bronchitis*, and troubled with what they call crude phlegm, or much mucous expectoration, are apt to fall into a fatal decay, as a consequence of an acute attack originating in cold; and others, who have been in a lingering state of health for some time, with a slow fever and a short dry cough, or a cough accompanied with expectoration, especially in the morning, of clear and frothy sputa, are prone to have their fever increased, and to be hurried into a state of catarrhal consumption. In cases of the latter kind, it is probable that tubercles may have previously existed in the lungs, and that the exception of catarrh only serves to bring phthisis into more decided action. And, indeed, it may be made a question whether those cases of chronic bronchitis to which I have referred may not, sometimes at least, be instances of bronchial irritation, and consequent expectoration of a mucous secretion, sustained by the presence of tubercles. Whatever be the particular form or primary character of pulmonary consumption, certain states of the atmosphere, depending on different degrees of altitude, appear to be either hostile or favourable to its existence or development, according to the particular locality in which the patient happens to reside. Thus on the coast it is a common disease, terminating in purulent expectoration and death, in whatever way it may have originated; but on the intermedial mountains, and in the temperate valleys of the interior, pulmonary consumption is a rare malady.

"A failure of strength and health coming on gradually, or as it were by stealth, with impaired appetite, a slight dry cough, with or without pain at the breast or shoulders, a febrile pulse, with nocturnal heat and restlessness, are symptoms frequently precursory of those which characterize confirmed consumption. This slow fever, so much dreaded by every one as the harbinger of phthisis pulmonalis, and often aggravated by daily provocations, or fretfulness and anger, is always accompanied, if not always preceded, by a diseased condition of the digestive functions. This affection is, I think, well described by Tissot as a disease to which men of letters are subject: 'This slight fever, to which some men of letters are liable, and which, by impairing the nutritious lymph, renders them pale and thin, and throws them at last into a state of decay and consumption, a fever which itself depends on this, that sometimes a strong mental emotion excites the action of the heart and accelerates its pulsations; but more frequently it arises from bad digestion, and a faulty condition of the chyle, which irritates the organs of circulation, and so becomes the cause of the fever; and, also, if the organs of respiration are delicate and sensible, of a cough, which, united to the fever may degenerate into hectic fever and phthisis.'—*De la Saleté de Gens des Lettres*, p. 33. In conformity with these views, which are as applicable to the ordinary cases of incipient phthisis in Lima, as to the explanation of the origin of pulmonary affections in men of letters, according to Tissot, I would remark that the chests of the Linoenos, especially the male part of the white population, are commonly contracted; very rarely open and spacious, except among the dark and labouring classes; and every practitioner entrusted with the medical treatment of these people should constantly bear in mind that their respiratory organs are so delicate and easily affected, that sometimes shaving and washing the face in cold water bring on catarrh; and I have already shown how this latter affection may be the precursor of confirmed consumption."—*Edinburgh Medical and Surgical Journal*, vol. liv., p. 6-9.

Dr. A. SMITH has here shown the very intimate connexion of phthisis with impaired digestion and assimilation, and the want of originality, as well as the limited views of those writers who, since the days of Tissot, have espoused a somewhat similar doctrine. Of *hemoptysis*, in connexion with phthisis in Peru, Dr. A. SMITH remarks: "Spitting of blood from the lungs is exceedingly common in Lima; and not confined to persons of any particular class or colour, though more prevalent among the fairer inhabitants of European descent;" and he points out the frequency of attacks of *hemoptysis*, not only as a prelude, but as an attendant upon the early stages of consumption among the several races peopling Peru.

sis.—Before a precise idea can be formed of the states of the blood in this disease, the healthy conditions of the blood should be considered, with reference to *sex, age, and temperament*, in order that the degrees in which the former differ from the latter may be seen. It should not, however, be overlooked that the *chemical analyses* of DENIS, LECANU, BECQUEREL, RODIER, ANDRAL, NASSE, GAVARRET, SIMON, &c., have presented slight differences, even at the same age, in the composition of the blood in health, so that the results at which they have arrived may be viewed rather as a close approximation to the truth than as absolute certainty. In addition to the differences arising from sex, age, and temperament, others, hitherto not inquired for, may also exist, especially those depending upon race, climate, and season. After examining the mean results furnished by the above writers, I here give those assigned by BECQUEREL and RODIER, as the most precise and as nearly approaching the mean of the other observers.

98. a. The following table, containing the mean of a number of analyses of the blood of *healthy* persons, between the ages of 21 and 55 years, shows the differences between the constituents of this fluid in *males* and *females*, in 1000 grains, or parts.

	Male.	Female.
Density of defibrinated blood	1060.0	1057.5
Density of serum	1028.0	1027.4
Water	779.0	791.1
Fibrin	2.2	2.2
Sum of fatty matters	1.60	1.62
serolin	0.02	0.02
phosphorized fat	0.488	0.464
cholestrin	0.088	0.090
saponified fat	1.004	1.046
Albumen	69.4	70.5
Blood-corpuscles	141.1	127.2
Extractive matters and salts	6.8	7.4
chloride of sodium	3.1	3.9
other soluble salts	2.5	2.9
earthy phosphates	0.334	0.354
iron	0.566	0.541

99. b. The differences of the constituents of the blood at different *ages* have not been determined with sufficient precision; but, according to the researches of DENIS, the water in the blood is somewhat increased after 50 years of age, the solid residue slightly less, the blood-corpuscles are materially diminished, and the albumen nearly the same in quantity. In *childhood*, the water is increased, the solid residue somewhat less, the blood-corpuscles considerably less than at mature age, and the albumen nearly the same as at that age. BECQUEREL and RODIER state that, after 40 or 50 years of age, there is a decided and progressive increase of cholestrin in the blood. As puberty approaches, and as the generative organs are developed, the blood-corpuscles and iron increase, and the relative proportion of water diminishes; the corpuscles and iron serve to maintain the energy of these organs; and until the powers of these organs begin to flag, the blood experiences little or no diminution of its red corpuscles.

100. c. The *constitution* has considerable influence on the state of the blood. At equal ages, the solid constituents and hæmato-globulin are less abundant in the blood in weak than in strong constitutions. According to LECANU and others, the blood of persons of *lymphatic* and *phlegmatic*

temperaments is much poorer in solid constituents, and especially in red globules, than that of persons of sanguineous temperament—the quantity of albumen being the same in all. The following are the results in 1000 parts :

	Sanguineous Temperament.		Lymphatic and Phlegmatic Temperament.	
	Men.	Women.	Men.	Women.
Water . . . . .	786.584	793.007	800.566	803.710
Albumen . . . .	65.850	71.264	71.781	68.660
Blood-corpuscles .	136.497	126.174	116.667	117.300

101. *d.* The chemical analysis of the blood in threatened and incipient phthisis furnishes the same results as those stated in the article on SCROFULA AND TUBERCULOSIS (§ 93, *et seq.*). When phthisis is farther advanced, the changes in the blood are more and more manifest. ANDRAL and GAVARRET state that, in all periods of the disease, excepting the last, the fibrin seems on the increase, and the red corpuscles are on the decrease, progressively throughout; but that the proportion of the increase on the one hand, and decrease on the other, varies with the progress of the malady. If the tubercles be in a crude, unsoftened state, the increase of fibrin is only small, and its whole amount may be estimated at about 4. This, however, according to the researches of Dr. FRICKE, of Baltimore, and others, is too high an estimate. The decrease in the corpuscles in this stage is perceptible, but not very great. As the tubercles soften, the quantity of fibrin slightly increases, and the corpuscles decrease. Upon the formation of vomica, or cavities in the lungs, the fibrin is somewhat farther increased—to 5.5 according to ANDRAL—but it never reaches the amount observed in pneumonia. The results vary, however, with the nature of the associated lesions, which most of chemical observers have not taken into the account; for the occurrence of severe attacks of hæmoptysis, or of partial, sub-acute, or chronic pneumonia, or pleuritis, or peripneumonia, will increase the fibrin and greatly diminish the red globules. In the last stage of phthisis the blood becomes still poorer; the fibrin decreases in nearly the same ratio as the other solid constituents, and even often falls below the healthy standard. The following table furnishes the results of 22 analyses by ANDRAL and GAVARRET, and 9 by BÉCQUEREL and RODIER, in 1000 parts of the blood in phthisis :

	In Men.			In Women.	By Andral & Gavarret.

102. Mr. ANCELL has adduced the results of a great number of researches into the constitution of the blood in phthisis. He views the disease to derive its origin from morbid states of the blood. The chief differences existing between the views of that gentleman and those entertained by me, as stated under the head SCROFULA AND TUBERCLES (§ 101, 102), are, that I consider the changes observed in the blood, the nature and extent of

which I fully admit and describe, not as the origin of tuberculosis, but as effects of originally deficient, or consecutively impaired, power of the organic nervous system—of that system which endows the digestive, assimilating, circulating, and nutritive organs—defective assimilation of the chyle, and an unhealthy condition of the blood, being the consequences of this state of the organic nervous system, and only intermediate links in the chain of pathological results, the extremities of which chain are the state now assigned and the tubercular lesions.

103. *c.* I may adduce the following as the results of my own observations of the state of the blood in the early and in the advanced stages of phthisis: At an early period, or even before the disease has fully declared itself, the blood is thinner or poorer than in health; the colourless globules are more or less abundant, and the red globules less numerous; the clot is somewhat smaller, its crasis less, and it sooner loses its cohesion. As the disease advances, and as febrile action is established, the fibrin is somewhat increased, and this is more certainly the case, if hæmoptysis, or intercurrent inflammations of any of the pulmonary structures take place; the red globules are diminished, and the albumen and fatty matter are not very materially changed in quantity. The alkaline salts are slightly deficient, and lime is somewhat in excess. It should not, however, be overlooked that, among the numerous analyses of the blood in phthisis, there are very great differences in the quantity of fibrin, of albumen, and of fatty matter. I have here given what appears to be the more correct results. Probably the quantity of each of these is not so different as the quality, the intimate constitution, and vital relations. In the last stage of the disease the blood appears still more watery, owing chiefly to the deficiency of red globules; and the colourless globules more numerous than in health. The greater abundance of colourless globules is probably owing to impaired assimilation, or metamorphosis, of these into red globules. The colourless globules in this, and indeed in earlier stages of the disease, have been mistaken for pus globules, the existence of which in the circulation is doubtful, or at least not satisfactorily demonstrated. The vital crasis, as well as the size of the clot, progressively diminishes. It does not appear that the microscopic appearances of the blood in phthisis are different from those now stated, or that the observations which have been made with the aid of this instrument have furnished any additional facts to those now adduced. (See art. SCROFULA AND TUBERCLES, § 93, 94.)

[It must be acknowledged that we are as yet imperfectly acquainted with the true nature of the tuberculous crasis. It is evidently a special *dyscrasia*, connected with causes of debility which induce such changes in the circulating fluid as to lead to the deposition of a substance exhibiting the feeblest traces of organization. This matter would seem to bear little resemblance to fibrin; and yet ROKITSKY seems to regard it as a modification of fibrin, and concludes that "the arterial character—arterial elaboration of the fibrin—constitutes, above all, the cardinal feature of the tuberculous crasis." He also points out how, in consequence of the alteration of the nature of the fibrin, tubercle is continually deposited, even when the blood is very deficient in that constituent; the fibrin that is formed being soon affect-

ed by the peculiar dyscrasia, and deposited in the form of tubercle. The rapid coagulation of tubercle-blastema, which must be effused in a fluid form, its tendency, when coagulated, to soften—its formation being favoured by active arterialization, and prevented by a venous condition of the blood—are circumstances which indicate a real affinity between tubercle and fibrin. When we reflect that various debilitating causes are found to increase the quantity of fibrin, and also that the same are potent in causing the production of tubercle, this hypothesis acquires farther probability. But in a majority of cases, even before this peculiar modification of fibrin has taken place, which leads to its excretion in the form of tubercle, a special impress is stamped upon the system, which betrays to the experienced eye the approaching evil. Its phenomena mark the scrofulous diathesis, so called. There is an opposite diathesis, or condition of the blood, characterized by deficiency in fibrin and excess of albumen, and generally also of blood-globules, which is called by ROKITSKY *venosity*, or *albuminosis*, and by SIMON *hypinosis*, and in which tubercular deposits are extremely rare.]

104. v. COMPLICATIONS OF TUBERCULAR PHTHISIS.—It is manifest that tubercles in the lungs, in their several states and stages, being the effects (as shown in the *art.* SCROFULA and TUBERCLES, § 101, 102) of originally deficient, or subsequently impaired, organic nervous power, and of the consequent changes in the blood, should not be viewed as a special disease of the lungs, or as limited to these organs only, but as a malady, in which the constitution—the whole frame, is more or less implicated. The earlier changes of organic nervous power and of the circulating fluids being such as now stated, it may be inferred that numerous associated and consecutive alterations will appear at early and advanced stages of the malady, more or less intimately connected with the original mischief, or tubercular vice, either as associated or related changes, or as more remote results. As these severally, and often in various associations, may be expected to present themselves in the course of phthisis, it becomes important that a brief view should be taken of them, as they are most frequently presented to us in actual practice, and nearly in the order as to frequency in which they occur.

105. It will appear from the foregoing, as well as from the circumstance of my not having taken particular notice of a form of phthisis, recently called *dyspeptic phthisis*—a form which Dr. A. SMITH has shown above (*see note to § 96*) to have been first insisted on by TISSOT—that I do not consider this as a variety of phthisis, inasmuch as indigestion is, as noticed by Dr. SMITH, an early attendant upon all the forms of this malady, although in different grades; and even when dyspepsia may be so slight as to be overlooked, especially as regards the functions of the stomach, healthy assimilation and nutrition may be very remarkably impaired. Original or acquired defect of the digestive, assimilating, and nutritive functions is not only the attendant upon the commencement and progress of the several forms of phthisis, but it precedes their origins in more or less manifest grades. Indeed, the malady may rationally be viewed as presenting this procession of morbid phenomena. If we admit the earliest change from health in tubercular persons, whether hereditary or acquired, to be impaired function

of the ganglial nervous system, or, in other words, defective organic nervous power—a power which endows and actuates the digestive, circulating, and nutritive organs and functions.

106. A. HÆMOPTYSIS.—I have already considered this occurrence as a symptom of phthisis (§ 49, *et seq.*). It may also be viewed as a *complication* of this disease; and it may supervene upon tubercles of the lungs coexisting with either functional and congestive disorder, or with organic lesion, of the heart. Hæmoptysis may, however, be caused by congestion of, or impeded circulation through, the cavities of the heart, independently of the existence of tubercles in the lungs; but this occurrence is comparatively rare. The blood may proceed: 1st, as a simple exudation from the bronchial mucous membrane, in consequence of the irritation and congestion caused by the tubercular deposits, whether within or without the air-cells and capillary bronchi, and by the impediment they occasion to the circulation in the pulmonary veins; 2dly, from the surface of a cavity owing to the erosion of one or more of the vessels passing to it—a circumstance of much more frequent occurrence than was formerly supposed; 3dly, into the structure of the organ, without any previous cavity, little or even none of the blood being expectorated, asphyxia having been suddenly produced by the extravasation. (See § 134, and *art.* LUNGS, § 186, *et seq.*)

107. The hæmoptysis which takes place at the commencement or at an early stage of phthisis may generally be ascribed to the first of these pathological states; but it may also proceed from the disorders and lesions of the heart already alluded to (§ 51), either independently of, or in connection with, tubercular deposits in the lungs. It should not, however, be overlooked that the hæmoptysis may appear in females as a vicarious menstruation; and as such it may be connected with tubercular deposits in the lungs or morbid states of the heart, or with both states of disease, or it may be independent of either of these. When the hæmoptysis takes place vicariously of menstruation, the lungs are very rarely free from tubercular formations. But, in whatever mode hæmoptysis takes place, the blood, which remains for a time in the bronchi, from or into which it is effused, generally excites more or less irritation, often amounting to inflammation of the bronchial mucous surface, thereby farther complicating the malady. (See *art.* HÆMORRHAGE from the respiratory organs, § 96, *et seq.*)

108. B. BRONCHIAL IRRITATION AND INFLAMMATION.—Bronchitis, most frequently limited, but either acute, sub-acute, or chronic, is a common complication of phthisis. It may exist in one or other of these states. It is generally confined to the bronchi in a portion of one or both lungs, and more especially to the bronchi in the vicinity of, or communicating with the seats of tubercular deposits or cavities. In the first stage of phthisis, these deposits most probably occasion merely a state of irritation, or of sub-inflammation, of the mucous membrane of the adjoining bronchi; but, even in this stage, when external agents or other causes aid the operation of this pathological condition, then a more active disease of this membrane is developed, especially if one or more attacks of hæmoptysis have occurred, and sub-acute or even acute bronchitis results. The effect of this bronchitis, although limited, as now stated, is to develop the crude tubercles and to hasten

their softening. When this has taken place, and the softened tubercular matter has made its way into the adjoining bronchi, then a very obvious cause of irritation and of inflammatory action is superadded to those previously existing. Hence during and subsequent to the softening—during the second and third stages, the sputum becomes much more abundant, and its quantity is owing chiefly to the morbid secretion from the inflamed bronchi—unless, indeed, in those very rare cases when the bronchi are not materially irritated by the disseminated tubercles, or when the softened matter is absorbed and does not pass off by the bronchi. In these stages, the discharge from the surface of the cavities, or the contents of recent tubercular vomicae, are the chief causes of the bronchitis and of its perpetuation; for it is frequently observed that the morbid appearances, both inflammatory and ulcerative, exist chiefly in, or are limited to, the bronchi communicating with the vomicae or cavities, and that these changes may be traced in and from these bronchi to their larger trunks, until the trachea is reached, where also, as well as in the larynx, the same alterations are not infrequently observed (§ 109, 110); while the bronchi which present not this communication, or which extend only to crude tubercles, are either exempt from these changes or present them in a slight degree. Dr. CARSWELL detected ulceration even in the minute bronchi communicating with cavities, showing the extension of the morbid action from the latter by means of the discharge from them.

109. *C. INFLAMMATION, ULCERATION, OEDEMA, &c., OF THE LARYNX AND TRACHEA* are often complications in the course of phthisis. The frequency of this association depends upon the original, concurrent, and consecutive causes, and upon influences and agents acting in the course of the malady. The affection of these parts is to be imputed chiefly to the same changes as occasion the bronchitis—to the tubercular and other discharges from the originally diseased parts; and often the morbid appearances may be traced from the bronchi communicating with cavities to the trachea and larynx. In some cases, however, the affection of the larynx, and even of the epiglottis, commences previously to the softening of the tubercles, and may be ascribed in these to the greater susceptibility of these parts, in the early stages of phthisis, to the usual exciting causes of inflammation and its consequences, and to the irritation extending to them—by sympathy and continuity from the pulmonary and digestive mucous surfaces. In the early, as well as in the advanced stages of phthisis, the digestive mucous surface furnishes many indications of irritation, giving rise to heart-burn, acrid eructations, &c., which very sensibly affect the larynx and epiglottis, and kindle disorder, which is not readily, and even never, put out. That it may thus partly originate in the digestive organs, is shown by the circumstance of the lesions being sometimes either limited to the larynx and laryngeal surface of the epiglottis, or chiefly found in these parts, the trachea being comparatively exempt or nearly so. In other cases, both these and the trachea are affected more or less; and not infrequently the inflammatory changes, ulcerative, &c., are limited to the trachea, and found chiefly either in the posterior or membranous portion of the trachea, or towards the side of it corresponding with the cavities which exist chiefly or only in one lung.

This limitation of the ulceration to one side of the trachea very probably is caused by the passage of the morbid secretion over it during the position of the patient in bed, which is most frequently on the back, or towards the side most diseased, so as to give greater freedom of respiration to the lung least affected. In some cases, the ulceration of the posterior part of the trachea is very extensive, and some of the ulcers very deep, even so much so as to give rise, in rare instances, to a fistulous opening into the œsophagus, one instance of which came under my observation. (See *art. LARYNX and TRACHEA*.) The larynx is rarely attacked primarily, or independently of tubercular deposits in the lungs; it is chiefly in connexion with tubercular disease of the lungs and with syphilis that lesions of this part occur. M. LOUIS states that of 180 persons who died of chronic diseases not phthisical or syphilitic, he found one only with ulceration of the larynx; but that one in five had ulceration of this part or of the epiglottis, and one in three had ulceration of the trachea, among those who died of tubercular consumption.

110. *Inflammation or ulceration of the larynx* is an important complication of phthisis; and when the affection of these parts is severe, and that of the lungs not well developed, or at an early stage, the disease has often been called *laryngeal phthisis*. But in those cases the affection of the larynx is merely symptomatic of the tubercular formations in the lungs, which is often masked by the former affection, especially when it is severe or the tubercular deposits not far advanced. In this state of the larynx there is either hoarseness or loss of voice, with pain in the region of the os hyoides, especially when ulcerations have advanced. The cough is characterized by a harsh, grating sound. It is difficult, suffocative, or attended by a whistling noise. The ulcerations in the trachea are very frequent in the more chronic states of phthisis, and are rarely manifested during life in these slow cases. M. LOUIS observed in some instances that sensations of heat and obstructions were complained of behind and above the sternum.

[It is well to bear in mind that all the rational signs of pulmonary phthisis may be present, including emaciation, profuse sweating, cough, purulent expectoration, mingled with blood, hectic, derangement of digestive organs, &c., without the presence of tubercular deposits in the lungs, but from laryngeal and bronchial disease. Such cases can only be distinguished by a careful auscultatory examination of the lungs and larynx, and actual inspection of the pharynx. In the same manner, chronic bronchitis is often confounded with, or mistaken for, simple throat disease. Dr. BENNETT has remarked very truly that, even when pulmonary tuberculosis does exist, many of the urgent symptoms are not so much owing to disease in the lungs as to the pharyngeal and laryngeal complications; and that local treatment may not only remove or alleviate these complications, but that, in conjunction with general remedies, it tends in a marked manner to induce arrestment of the pulmonary disease.]

111. *D. INFLAMMATIONS OF THE LUNGS, limited to portions of them, and both of these portions and of their bronchi*, especially to parts adjoining the tubercular masses, vomicae, and cavities, often occur at all stages of phthisis. In the first stage, when the tubercles are crude, or disseminated

through the organ, the inflammatory action may, from its grade, or its congestive or scrofulous character, or from being masked by the tubercular deposits, be imperfectly manifested either by the rational symptoms or the physical signs. In this stage it is very difficult to determine whether the tubercles be the cause of the inflammatory irritation, or the latter the produce of the tubercles. It is not improbable that, however originating, the one morbid state acts, and is acted, on by the other. As the tubercles advance to softening, inflammatory or congestive appearances may be detected around them, and the same are often seen around the vomica or in or near the walls of cavities, the bronchii, both capillary and large, participating in these changes. In many instances the structure of the lungs is condensed or infiltrated with tubercular matter around cavities or vomica, the change being a result of inflammation of a scrofulous or congestive character, limited to the situations in which the tubercular deposits are, or have been, most abundant or developed. In other instances, especially at an early stage, the attacks of hæmoptysis, especially when considerable, diminish or subdue the inflammatory condition, and leave the portions of lung not yet disorganized in a better state than previously for the performance of their functions. In some cases, especially where the deposits or vomica are near the surface of a portion of lung, the inflammatory action in the adjoining structure extends to the pleura, giving origin to the next complication, namely, intercurrent *pleuritis*, which is very frequently associated with one or more of those already considered.

112. *E. INFLAMMATION OF THE PLEURA*—in an acute, sub-acute, or chronic form—most frequently limited, but sometimes very considerably extended—generally very sensibly expressed, but occasionally almost latent or not expressed, or rather overlooked during life, is a most common lesion in cases of tubercular consumption; for it is very rarely found on dissection that the lungs in this disease are altogether free from old or recent adhesions. The pleuritic lesion usually arises as just stated, and is in most cases manifested by the pain commonly experienced, and if not by pain, by the physical signs. The inflammation of the portion of pleura covering tubercular deposits or vomica agglutinates it, by the exudation of lymph, to the opposite or costal pleura, thereby preventing, unless in rare instances, the *perforation* of the pulmonary pleura, and the consequences which would follow. The lesions supervening in the pleura in the course of tubercular phthisis, and the contingent results which sometimes ensue, more especially *perforation of the pulmonary pleura*, are fully considered under the heads *PLEURA, Inflammations of* (§ 112, *et seq.*), and *structural Lesions of* (§ 201, *et seq.*), and *PNEUMOTHORAX*, and to these I refer the reader for the farther elucidation of these complications of phthisis.

113. *F. SEVERAL ABDOMINAL COMPLICATIONS* are manifested in the course of phthisis, and evince the general or constitutional nature of the malady—or the origin of it in the organic or ganglionic nervous influence endowing the vascular system and the circulating fluids. These complications may appear at all stages of phthisis, or they even may precede the first stage.—*a.* The complication with *disease of the digestive mucous surface* is one of the most important. The stom-

ach, the lower parts of the ileum, and the cæcum and colon, are most frequently affected. M. ANDRAL justly remarks that “softening of the mucous membrane of the stomach, hyperæmia of the different portions of the intestines, ulceration of the small intestine, accompanied in many instances by a development of tubercles, are all of such frequent occurrence in phthisis, that they may fairly be considered as constituent parts of the disease.” These lesions of the digestive canal most frequently occur in the course of the pulmonary disease, often not until an advanced stage, especially in persons somewhat advanced in age; but they sometimes precede it, particularly in children and younger subjects; and, in some cases, the pulmonary and abdominal affections appear to commence at the same time or nearly so.

114. (*a*) This is more especially the case as respects the complication with *disorder of the stomach*. At the commencement of phthisis this complication is usually of a dyspeptic character; but it may, as the disease advances, or even from the first, assume a severer form, and be attended by nausea, pain, or vomiting. Tenderness, a sense of heat or burning pain, increased by pressure, are present in these cases, and may arise either from inflammatory softening of the villous surface or from ulceration. These symptoms and lesions, although early observed in some cases, the vomiting and pain occasionally being severe and obstinate, commonly appear in the second or third stages of phthisis—oftener in the third. As far as my experience extends, young females have more frequently presented this association than males. *Increased size of the stomach* was observed by M. Louis in more than two thirds of the cases examined by him after death, while only two instances of it were seen in 230 subjects who died of other diseases. In some cases the organ is double or treble its natural capacity, descending in these as low as nearly to reach the pelvis, its coats becoming thinner in the ratio of its increased size.

115. (*b*) *Disease of the intestines*, chiefly of the follicles of the lower portion of the ileum, commencing with tubercular deposits in the solitary and agminated follicles, and terminating in ulceration of these, is a very common complication of phthisis. The follicles are first distended, enlarged, and projected on the mucous surface by the tubercular deposit; they afterward burst, discharge their contents, and ulcerate, the ulcers being seated chiefly in the patches of agminated follicles in the lower portion of the ileum, and in the side opposite to the attachment of the mesentery. In the large intestines, especially the cæcum, the ulcerations are disseminated irregularly. The small ulcers in the ileum generally coalesce, and the ulcers often pass under the mucous surface and detach portions of it. They often proceed deeply, as shown in the article on the *DIGESTIVE MUCOUS SURFACE* (§ 36, *et seq.*), but they rarely perforate the intestines in phthisis, for as soon as they approach the peritoneal surface, lymph is thrown out on it, and the nearly perforated part is agglutinated to the opposite peritoneal surface. This lesion of the intestines is generally attended by the obstinate diarrhœa which occurs in the second and third stages of phthisis, in the latter especially, and has usually been termed *colliquative diarrhœa*. It is chiefly to be ascribed to two morbid conditions, or to either of

them, namely, to the existence of tubercles in the intestinal follicles, or to disease of these follicles excited by the morbid states of the blood, in the course of the elimination of the morbid elements from this fluid by these follicles.

116. The earlier the ulceration of the intestines takes place in phthisis, the more rapid in general is the progress of the malady, and the loss of flesh and strength of the patient. In the more chronic and protracted cases, this lesion seldom supervenes until shortly before their fatal termination. M. LOUIS states that he found tuberculous ulceration of the small intestines in five sixths of the cases he inspected, and almost as frequently in the large intestines, the mucous membrane being often red, thickened and softened in about one half of these cases. In the whole number of phthisical bodies examined by this physician, the large intestines were in a healthy state throughout their extent in three instances only. In the cases which I have inspected, I have always found the *cæcum* more or less ulcerated; and in some I had reason to infer that this portion of the canal was the first to be affected; perforation of the *cæcum* and pericæcal abscess, or fistula, having taken place in two cases in which I was consulted.

117. (c) The *mesenteric glands* are often found tuberculous, especially in young subjects, and in connexion with tubercular ulceration of the intestinal follicles. In the phthisis of very young children these glands are rarely exempt. PAPA-VOINE says that he found this lesion in one half of the cases of phthisis in children. This proportion is less than I have remarked in this class of subjects. In adults, LOUIS found these glands tuberculous in one fourth only.

118. (d) The *liver* is found remarkably changed in a very large proportion of phthisical cases. This change consists in the deposition of *fat* in its structure, this organ becoming enlarged, fawn-coloured, and of diminished consistence, in proportion to the amount of fatty degeneration. The fatty or oily nature of this change is at once shown by the scalpel on dividing the liver, or by pressing a portion of it on paper, or by subjecting it to heat. The organ is equally changed throughout, and with a rapidity nearly equal to that of the tubercular malady, with which this alteration is intimately connected, and upon which it is dependent. M. LOUIS states that of 49 cases of this degeneration, 47 occurred in tubercular phthisis; while of 230 subjects of other diseases, nine only presented this alteration of the liver, and seven of these had tubercles in the lungs. He farther remarks, that it is independent of the patient's age, and of any known cause excepting the existence of tubercles; and that it is not attended by any evident symptom except enlargement, the functions of the organ not being disturbed. Sex appears to influence its occurrence, as of the forty-nine cases seen by LOUIS only ten were males. The most remarkable instances of this alteration in connexion with phthisis which I have seen occurred in females addicted to the abuse of spirituous liquors. In a young female who was thus addicted from childhood, who had never menstruated, and had died of phthisis about the age of nineteen, the fatty, fawn-coloured liver was so remarkably enlarged as to fill the abdomen, the lower edge of it pressing upon the bladder and pelvic viscera, the organ nearly equalling in weight the whole body. In these cases, tubercles are

rarely found in the liver, unless in children. From my own observation, and from a remark made by Sir J. CLARK, this change of the liver is not so frequently seen in phthisical subjects in this country as in France, yet functional disorder of this organ is often observed in the course of phthisis.

119. *G. Various other lesions* take place, especially in the advanced course of phthisis, but these are merely contingent occurrences, and seldom or even rarely met with. The most important of these are lesions of the heart, in rare cases, occasioning sudden death in the course of phthisis, obstruction of veins from coagula in their canals, hæmorrhoids and fistula in ano, tubercular and granular lesions of the urinary organs, and disease of the sexual organs. These require merely a few passing remarks.—*a. Softening and slight dilatation* of the ventricles is sometimes observed in the course of phthisis. In the case of a lady, death took place suddenly in the second stage of the chronic form. The body was examined in my presence, and the only apparent cause of the sudden dissolution was this alteration of the heart. I have, however, seen this change in other cases of phthisis; but, although it may have accelerated the course of the malady, sudden death has not appeared to have been caused by it.

120. *b. Coagula in venous trunks*, especially in the extremities, form in rare cases at an advanced stage of phthisis, occasioning great œdematous swelling of the limb, and are the results of the morbid state of the blood and of impeded circulation in the venous trunks rather than of inflammation of these vessels.

121. *c. Hæmorrhoids* are occasionally a complication of phthisis, and are produced as much by one of the most frequent causes of the latter as by irritation of the rectum by frequent action of the bowels, and by interrupted or impeded circulation in the portal vessels, namely, by masturbation, which determines the circulation to the structures in the vicinity of the anus, and which, with one of its consequences, constipation of the bowels, favours congestion of the hæmorrhoidal veins.

122. *d. Fistula in Ano* sometimes occurs in the course of phthisis, more frequently in the early stages. It may be imputed to the same causes as produce hæmorrhoids. It has the effect of prolonging the duration, or, to a certain extent, arresting for some time the progress of phthisis. Hæmorrhoids, when they discharge at intervals, have a similar effect to fistula in ano on the progress of the disease, as I have observed in several cases.

123. *e. Alterations*, more particularly tuberculosis, of the *urinary and sexual organs*, seldom supervene in the course of phthisis, although the functions of these organs, especially of the uterine organs, are more or less disordered. Tubercular formations are sometimes formed beneath the mucous surface of the urinary passages in the phthisis of children: and in female adults the catamenia are generally delayed, painful, or suppressed in the advanced progress of the malady, which generally assumes a more severe and rapid form when this disorder supervenes. In a case of a young lady, who died about the age of twenty of phthisis, and who had never menstruated, the body was inspected in my presence, and the ovaria were found very small, and their coverings thickened and almost of a fibro-cartilaginous density. The disease had been attributed by me to mastur-

bation, the non-appearance of the catamenia, and the alterations of the ovaria, probably having been caused by this most noxious vice.

124. III. PATHOLOGICAL ANATOMY OF PULMONARY TUBERCLES.—On opening the thorax after death from phthisis, the lungs generally do not collapse, or collapse imperfectly. They are more or less increased in weight, in some cases very remarkably. Dr. CLENNENING found the average weight of the healthy lungs of an adult to be  $4\frac{1}{2}$  ounces; and Dr. BOYD, as stated by Mr. ANCELL, ascertained that in a considerable number of adult males the average weight of tuberculated lungs was  $7\frac{1}{2}$  ounces. The increase is due partly to the tubercular deposit, and partly, in various degrees, by an increased quantity of blood in the vessels, the secretion of tuberculous pus, serous effusion, red or gray hepatization of the lung, or extravasation of blood.

125. In the early stage of uncomplicated phthisis, when the tubercles are distinct, the pulmonary tissue is crepitant around them, and those which are most superficial somewhat raise the pleura. Distinct tubercles in the lungs, according to HASSE, are never larger than hemp-seeds; when they are described as larger, a congeries must be understood. Gray and yellow crude miliary tubercles seldom coexist in the same lung, unless they are deposited at distinct periods. (See SCROFULA and TUBERCLES, § 65–90.)

126. i. *The seats of tubercles in the lungs* are somewhat different in adult and young subjects. In adults tubercular deposits are chiefly aggregated in the upper lobes. Miliary tubercles are most abundant in the posterior parts of the lungs, and through the parenchyma at some distance from the pleura, but there are many exceptions to this distribution. In children the whole lung, or large portions of both lungs, are the seats of deposits, which have appeared to have taken place about the same time. CARSWELL attributed the earlier and the more abundant formation of tubercles in the apices of the lungs to the motion of these parts being more limited than those of the lower lobes. The former also are more exposed to the influence of cold externally, and are more accessible to the air in its varying state of temperature and humidity. LOUIS, ANDRAL, and others consider that tubercles are more frequent in the left than in the right lung. HASSE, however, disputes this, but I believe with insufficient reasons. The question as to the tubercular deposit being *within* the air-cells, or *external* to them, or, in other words, in the parenchyma of the organ, is still disputed. MAGENDIE, CARSWELL, SCHRÖDER VAN DER KOLK, and RAINÉY contend for the former; while ANDRAL, ANCELL, and others consider that tubercles may occur in either of these situations, and in any tissue where nutrition or secretion takes place. According to Mr. RAINÉY, the earliest indications of tubercles in the lungs are deposits of a transparent, or grayish, or yellowish substance in the air-cells, sometimes completely filling and distending them, the minute blood-vessels of the parietes of the cells surrounding the deposits being still perceptible. The deposits sometimes occur in a few only of the cells, but more frequently they fill all the cells of one lobule; and in this case they press upon these vessels, which soon disappear, the whole lobule appearing, after a while, entirely formed of tubercular matter. Tubercles in the lungs thus, according to CARSWELL, originally as-

sume the shape of the air-cells, and are somewhat acuminate in proportion to their projection into the bronchial tubes. When they have been of slow growth, or are deposited in large groups, and occupy numerous cells of a lobule, they resemble the sprout of a cauliflower, the pedicle occasionally extending far into the bronchial tube. In the lungs of ruminating animals tubercular matter is often seen plugging up the bronchial tubes. As the tubercle increases in size, the central parts become farther removed from the vessels by which this matter is deposited; and consequently these parts have the greatest tendency to lose their vital cohesion, and they consequently are softened, this process generally beginning at or near the centre of the tubercle. (See SCROFULA and TUBERCLES, § 78, *et seq.*)

127. ii. *The distribution of tubercles in the lungs* varies much with the age of the patient and the form of the malady. In adults, in the usual and more chronic forms, the tubercular deposit commences, although in different amounts, generally in the apices of both lungs, and descends gradually downward to the lower lobes, the larger and older cavities existing at the apices, smaller ones lower down, and accumulations of softened or crude tubercles, or of both, at the base. This cannot, however, be viewed as an absolute law. The tubercles also in one lung, as the left, may be generally farther advanced in all their stages than those of the right. Besides, one portion of a lung may be the seat of cavities or softened tubercles, all the rest, or the greater portion, of the lung being quite sound. Tubercles which are formed rapidly are generally miliary, and nearly equally dispersed through the lungs. In the more acute states of phthisis they are thus deposited, or are infiltrated more or less extensively or densely.

128. iii. *Lesions of the Lungs associated with Tubercles.*—A. *Pneumonia*, or inflammation of portions of the lungs, and its usual consecutive changes, are often found associated with the several stages of tubercles. The inflammation may have passed on to red or gray hepatization, and it may have preceded the tubercular deposits, or may have been consequent upon them, induced by the usual causes of pneumonia; or it may have been produced by the irritation developed and kept up by these deposits. It should not be overlooked that the changes taking place in the lungs of scrofulous subjects during inflammatory action may be attended by tubercular formations. Yet this may not necessarily be the case, and these formations may exist in the lungs even of scrofulous and sanguineous temperaments without inflammatory action in the lungs being produced by them, this action being chiefly a contingent or intercurrent result of causes unconnected with the tubercular disease.

129. a. According to LOUIS, GRISOLLE, HASSE, ANCELL, and others, *inflammation primarily attacking* the scrofulous subject may produce an exudation of lymph differing from the exudation occurring in pneumonia affecting the healthy person, chiefly in its tuberculous characters, and the disease may run its course, and the exudation may be absorbed; but as frequently, perhaps, the pneumonia of scrofulous subjects is followed by tubercular deposits and their usual consequences. ROKITANSKY calls this latter change hepatization with tuberculous deposit, which, not being absorbed, or becoming purulent, ultimately passes

into yellow tubercle. According to HASSE, this alteration is found more frequently in males than in females, and in persons from 18 to 25 years of age, than earlier or later in life.

130. The alterations produced by *consecutive* or *incurrent inflammation* of portions of the lungs during the progress of phthisis is manifestly much more frequent than the primary form. LOUIS states that he observed the results of the first stage of inflammation, commonly occupying a limited space of the lungs, in 23 out of 123 cases, and the stage of red hepatization, generally in the lower lobe, in 18 cases. He regards the invasion of pneumonia in these cases as preceding death only a few days, and not peculiar to phthisis, as he observed it as frequently in deaths from other chronic maladies. Although the patient may die of pulmonary tubercles without any inflammatory appearances, yet the tubercles are very liable to irritate and inflame the surrounding tissues, and to render the patient more susceptible of the operation of the usual exciting causes of inflammation.

131. *b.* This secondary pneumonia generally assumes the *lobular* or *vesicular form*, and seldom appears until the tubercles have been developed, or have formed aggregated masses, and occasioned irritation in the surrounding structure. The matter exuded by this state of inflammatory action around the individual tubercles, or masses is generally peculiar, scrofulous, and gelatinous, the spaces between being healthy. Sometimes, however, the inflammatory changes are not limited to the patches around tubercles, but extend to the vesicular structure of an entire lobule, and pass on to red or gray hepatization, or even assume in parts a yellowish colour, the pulmonary structure being quite impermeable to air, firm and friable, the tubercles contained in it being more or less softened. In this state of the disease, the associated or intercurrent inflammation presents the usual scrofulous characters, modified by the peculiar structure and antecedent tubercular deposit.

132. *c.* The alterations found after death from the *acute form of phthisis* (§ 84) present many of the appearances consequent upon inflammation of an acute form in the scrofulous diathesis, associated with tubercular deposits, either antecedent to or coeval with the inflammatory action. As in other cases of inflammation in cachectic or unhealthy constitutions, the changes produced by it are peculiar, being diffused, œdematous, and marked by loss of the usual vital cohesion of the tissues. HASSE has well described the appearances in these acute cases. He states that one or both lungs are diseased. I have always found both lungs remarkably affected, although not to an equal amount or extent. In very marked cases the lungs, from their apices to their bases, are loaded with isolated miliary tubercles, mostly yellowish and soft, but sometimes grayish and more solid. The yellow and soft tubercles are in the centres of red or gray hepatized structures, while the gray are imbedded in a texture loaded with a bloody serum. The lungs are tumefied, do not collapse when the chest is opened, are very dark-coloured throughout, preternaturally soft, and gorged by dark fluid blood and serum. The tubercles have every where the same appearance; the pulmonary structure around them, for about a line, is more or less altered, the intervening structure being still permeable. The bronchial mucous surface is either dark-red or violet.

Recent adhesions between the surfaces of the pleura are not seen. If adhesions exist, they have been formed previously to this disease. When the malady has been slower in its progress, the tubercles are more united into groups, or are more densely crowded at the apices and superior lobes than in the lower lobes.

133. *d.* In the more *chronic and usual forms* of phthisis, the alterations often associated with the tubercular deposits are those which are clearly attributable to chronic inflammatory action, and consist of hepatization of a red or gray colour, or of varieties of hue of which these are original types. The parts thus altered are dense, impermeable to air; the bronchi are filled with a dense whitish matter, and the natural structure cannot be traced, the part being firm, but friable, or readily torn. The cut surface is speckled with gray inclining to yellow, is diversified with white stripes and arborescent black patches, and is devoid of the granulations of acute pneumonia. The incision is not followed by any exudation, and pressure yields only a little turbid grayish fluid. The inferior lobe of one or both lungs is thus chiefly affected; the alteration proceeding upward, and meeting the tubercular deposits as they advance downward. According to HASSE, this associated inflammatory alteration, which differs from the effect of common pneumonia in the induration of the lung, invades only the lower portion of one lung only, while the tubercular deposits exist in both.

134. *B. Extravasation of blood* in tubercular lungs is met with in either a fluid or clotted state. 1st. It may occur as a simple exudation from the bronchial mucous surface; 2d. It may proceed from ulceration of the bronchi; 3d. Blood may be infiltrated into the parenchyma of the lungs in connexion with congestive pneumonia complicating tubercles; 4th. It may be infiltrated not only into the parenchyma, but also into the air-cells; 5th. It may be effused from a laceration of the structure of the lung; 6th. It may be effused from the ulceration of a number of capillaries in the parietes of a cavity, or of one large vessel; and, 7th. It may proceed from the rupture of a cavernous band, or of a vessel or vessels in such band. In most of these the blood is found either in a frothy or fluid state in the trachea and bronchi, or partially coagulated; and coagula are contained in cavities, and sometimes in the bronchial tubes. In these several forms, excepting the two last, the effused blood may become the seats of tubercles. Extravasation of blood is met with in all stages of tubercular phthisis. According to HASSE, it is found chiefly where tubercles have been rapidly formed in connexion with inflammatory action, or when the lungs are replete with densely clustered tubercles. CARSWELL considers that the sanguineous effusion is in many cases owing to the compression of the pulmonary veins by the tubercular masses, and to the consequent prevention of the return of the whole of the blood sent to the organ. Both of these explanations may be correct as respects different cases.\*

135. *C. Œdematous infiltration* of the lung is sometimes seen, but generally only to a small ex-

\* [Pulmonary apoplexy, or effusion of blood into the cellular tissue of the lungs, is very often a result of obstruction incident to heart-disease. It may coexist with tuberclosis, where death will often be sudden and unexpected; but pulmonary tuberculosis is rarely associated with cardiac lesions involving obstruction, and this is an important diagnostic fact.—*Am. Ed.*]

tent, and chiefly in the acute form of the disease, in the more cachectic and phlegmatic habits; or when phthisis is complicated with disease of the bronchial glands, or of the kidneys. RILLIET and BARTHEZ consider that serous congestion or oedema of the lungs is sometimes connected with the deposit of tubercles in children; that it may be produced by this deposit; but that it most frequently depends upon compression of the vessels by enlargement of the bronchial glands.

136. *D. Emphysema*.—Vesicular emphysema is frequently found in tubercular lungs, in chronic cases, in connexion with various other lesions, chiefly in the superior and anterior parts. It occurs at an early stage, generally in a diffused form, and is produced by the pressure of disseminated tubercles upon the minute bronchi; the more powerful act of inspiration filling the cells, while the less powerful expiration fails in emptying them. Emphysematous portions of the lungs rarely contain tubercles. But this alteration is seldom found to a great extent, and generally in cases where it had not been detected by the physical signs: "it is usually seen in the upper parts of the lungs, and often in conjunction with cicatrized and collapsed portions. The healing process, by absorption of the more liquid parts of tubercles and of tubercular vomice, by shrivelling the remainder, by cicatrization of the ulcers, and obliteration of blood-vessels and bronchial tubes," produces a vacancy in the space within the thorax, and this space is gradually, or more or less, filled up by the sinking inward of the walls of the chest, and by the dilatation of the air-cells in the adjoining still permeable portions of the lung; this latter result sometimes preventing the occurrence of the falling inward of the parietes of the thorax.

137. *iv. Softened or liquefied Tubercles*.—I have stated above (§ 126) the views of Mr. RAINY as to the softening of tubercles; and those of LAENEC, LOUIS, SCHRÖDER, VAN DER KOLK, HASSE, and others have been stated in the article SCROFULA and TUBERCLES (§ 78, *et seq.*). It is not improbable that the process of softening may not be limited to one only of the modes contended for by these pathologists, but that when it commences or proceeds in the centres of the tubercles, it may also be advancing in their circumferences, owing to the irritation produced by them, and to the fluid effused from the irritated tissues surrounding them; the softening thus advancing from the centre to the periphery, and from the latter to the former of the tubercle. Generally it is found that softening of tubercular deposits first takes place, conformably with the progress of the deposits, in those nearest the summits of the lungs, and proceeds downward. With the process of softening, the pulmonary tissues surrounding the tubercles become more vascular, and inflammatory or congestive changes take place, extending more or less in the parenchyma, and ultimately to the pleura, as already shown (§ 111, 112, *et seq.*). The results of the softening are, discharge of the liquefied matter into the bronchi communicating with these tubercles, and the formation of a cavity, which enlarges by successive tuberculation and softening, by continued discharge, and by the coalition of two or more softened tubercles and small cavities.

[ROKITANSKY calls the yellow tubercle the *croupo fibrinous*, in opposition to the gray, which is regarded as simply fibrinous. The former un-

dergoes two changes: 1st. *Cretification*, which consists in the gradual deposition of calcareous particles in the tuberculous mass, with simultaneous absorption of the animal matter, thus constituting a hard, irregular mass, surrounded by indurated tissue; 2d. *Softening*, where the texture of the mass becomes more lax and moist, till it eventually breaks up into a yellowish, diffuent, cheesy mass, which finally becomes a thin, whey-like fluid, of acid reaction, and containing minute floculi. Softened tubercle, when examined with the microscope, is found to consist, 1st. Of a fluid loaded with diffused granulous matter; 2d. traces of altered nuclei and cells; 3d. free oil, in the form of various-sized drops, and debris of the tissues. The *gray tubercle*, according to ROKITANSKY, undergoes only a kind of drying up into a horn-like substance (*obsolescence*). In some cases it is also the seat of tuberculous deposit. The gray tubercle would seem to be essentially distinct from the yellow; and when it undergoes softening, it is owing to the changes in the yellow tubercle, which is often mixed with it. The same author has called attention to the fact that the behaviour of the two kinds of tubercle corresponds with that of the fibrin, from which they seem to be derived, the gray resembling healthy fibrin in its tendency to contract and shrink up into an indurated mass; the yellow, like the croupous fibrin of coagula and exudations, tends to soften and break up into a fluid substance, the softening commencing, in both instances, in the central portion. The softening is undoubtedly aided by the hyperæmia, and consequent effusion in the pulmonary tissue surrounding the tubercular mass; but the tendency to softening differs very greatly in different cases, and is probably proportioned to the extent of the tuberculous crasis. Where this is great, the softening will go on very rapidly, and a cavity be speedily formed; but where the *dyscrasic* condition of the blood is slight, or improved by proper treatment, then there will be an exudation of fibrin, which will be developed into the so-called induration tissue, or fibroid callus, which either surrounds the tubercle, or forms a wall to and contracts the cavity, if one has already formed, thus favouring cicatrization. We speak now of cases where tubercle is deposited in *tubercoid* masses. The exudation of tubercle-blastema may take place very gradually, or with great rapidity; in the latter case it is usually associated with hyperæmia and inflammation, and tends rapidly to softening and decay.

It is believed that the *cancerous* crasis excludes the tuberculous. Typhus and the exanthemata rarely attack the tuberculous, though they are often followed by tuberculous disease. Sufferers from intermittents, goitre, and rachitis are seldom liable to tuberculous affection; and ROKITANSKY thinks that an especial immunity against tubercle is afforded by an abnormally venous condition of the blood from whatever cause; as congenital malformations of the heart or great blood-vessels; morbid alterations of the same; deformities of the chest, producing contraction of its cavity; annihilation of the function of one lung by pleuritic effusion; abdominal growths, preventing the free descent of the diaphragm; chronic pulmonary catarrh; emphysema and bronchial dilatation; pregnancy, &c.; all which conditions interfere more or less with the due oxygenation of the blood. Tuberculous and scrofulous matter have the same elementary composition, undergo the

same changes, are produced in the same way, and produce the same effects on the tissues in which they are deposited, and hence may be well regarded as identical; and the organs are the seat of tubercle in the following scale of frequency: lungs, intestinal canal, lymphatic glands, larynx, serous membranes, brain, spleen, kidneys, liver, bones, periosteum, uterus, Fallopian tubes, testicles, prostate gland, spinal cord, voluntary muscles; except in children, where the order is lymphatic glands, spleen, lungs, brain, &c.]

138. *v. Tubercular Cavities and Vomicae.*—*A.* Tubercular vomicae, as Mr. ANCELL justly states, are either, 1st, pulmonary; 2d, pleuro-pulmonary; 3d, broncho-pulmonary; or, 4th, broncho-pleuro-pulmonary, according to their connexions with the principal structures of the lungs. The most frequent seat of vomicae and cavities is the summit of the superior lobes of the lungs. They are sometimes seen only on one side, tubercles on the other side being still crude or softening; but when the disease is of long duration they have formed on both sides. When they are found in the lower lobes, or at the base of the lung, they are generally more numerous, larger and older in the summit. Proceeding from above downward, the following grades or succession of tubercular alterations are observed: 1st, old cavities, with firm or almost smooth parietes, generally empty; 2d, more recent cavities with tuberculous deposits in their walls, or softened irregular parietes, containing matters about to be noticed; 3d, softened tubercles, either isolated or aggregated; 4th, crude tubercles; 5th, semi-transparent gray granulations; and, 6th, healthy crepitant lung. This succession arises from the progressive development of the tubercular deposit from the summit to the base. The cavities are generally seated deep in the lung, but in some cases they are superficial or near to the pleura. In the former case they commonly open into the bronchi; in the latter they are disposed to perforate the pleura, but are prevented by the adhesions formed by this membrane (§ 112). Large excavations are usually seated nearer to the posterior than to the anterior surface of the lungs, where they extend to the interlobular fissure, and even sometimes communicate with other cavities in the lobe below.

139. *B. The dimensions and form of the cavities vary much.* Their size varies from that of a pea to that of a large orange; small cavities are generally spherical or oval; but as they enlarge, their form is more irregular, owing to the softening and disorganization of the parietes having proceeded more rapidly in one direction than in another. Where several large cavities communicate, one unequal and sinuous excavation is formed, sometimes with fistulous tracts, and is very irregular in shape, direction, and size, but terminating in one or more ulcerated bronchi. The number of cavities is often considerable, the largest frequently arising from the union of several small ones. A single excavation is comparatively seldom met with. A cavity is surrounded by crude miliary tubercles, with very rare exceptions.

140. *C. The contents of excavations may be air; or viscid, purulent, or sanious fluids, containing whitish, curdy, tubercular matter, more or less softened; or purulent secretions of a dirty grayish, or yellowish, or yellowish-green colour, sometimes streaked, tinged, or mixed with blood; or blood more or less pure, fluid or coagulated. The fluid puriform contents are sometimes fetid, owing*

to their long retention, a communication with a bronchus not having been formed. Old cavities are often empty; recent ones frequently contain purulent or sanious matters, and the softened remains of tubercles. These matters are thus the secretion from the parietes of the cavity, and the debris of tubercles and of the surrounding tissues, altered more or less by retention in the cavities or by the action of the air. Fragments of the pulmonary structure are seldom found in the excavation, but when seen they are more frequently attached to, than detached from, the parietes. Bridles or cords are occasionally found stretching across a large cavity: these consist of blood-vessels, whose coats had become inflamed and thickened, their contents coagulated, and, having resisted the disorganizing process of the adjoining tissues, had been reduced to cords.

141. HASSE describes the blood-vessels forming bands across cavities as often having their coats reduced to a single, uniform, lardaceous substance; and their canals, which still continue, although narrowed, become eventually filled with a thin, reddish, fibrinous plug. The bands, or cords, thus formed by the blood-vessels are, in rare cases, either partially destroyed or torn asunder, before their canals are completely closed; and thus the more violent attacks of hæmorrhage ensue, and often prove fatal, the cavity and bronchi corresponding being found full of coagulated blood, and which also often fills, in a frothy state, the trachea. The bronchi are early destroyed; but, even when completely ulcerated, they often do not admit air into the cavity, nor the exit of the matters contained in a cavity; for they are plugged by lymph formed within the parts nearest the cavity, or by tubercular matter or deposits formed within them. The bronchi are not found in these bridles, which are thinner in their middles than at their extremities, the former having been longer exposed to the morbid processes.

142. *D. The parietes of cavities,* when recent, are merely the pulmonary tissues somewhat condensed by exuded lymph, or infiltrated with a grayish matter, or with gray granulations and crude tubercles. They are very rarely smooth, and formed only of the condensed pulmonary texture. In rare cases they are coloured by a brownish or blackish melanotic deposit. External to these parietes, which may not extend above a line or two into the pulmonary structure, the parts immediately surrounding them are healthy and crepitant. Somewhat older cavities are lined with a slightly adherent and soft false membrane. This lining is friable, white or yellowish, resembles concrete pus, and has no vascular connexion with the surrounding tissues. It seems as a deposit on the surface of the cavity from the matters therein contained. In still older cavities, external to this deposit, a membranaceous, organized layer, of a grayish fibro-cellular substance, is formed, and is closely adherent to the pulmonary structure. This constitutes the true cyst or parietes of the cavity. This capsule becomes after a time more organized, and, from fibro-cellular, it is fibro-serous, semi-transparent, and in patches, or more extensively fibro-cartilaginous, unless where bronchi pass into the cavity. These latter changes are observed only in very old cavities; and vary in colour, vascularity, density, and appearance, with their duration. The internal surface of these parietes or capsules no longer presents the concrete matter first deposited, and forming the car-

ly false membrane, but appears, at a much later period, smooth or velvety, and of a pearl-gray, pinkish, or reddish hue.

143. *E. The discharge or the absorption of the contents of vomica* are matters of interest. The discharge takes place by means of the bronchi, which are destroyed in the seats of vomica, and which become irritated, inflamed, and ulcerated by the matters formed and passed along them; the discharge from the bronchi, communicating with cavities, being often greater than that proceeding from the latter. When the matters contained in vomica are long retained without having communicated with bronchi, they often become very offensive and irritating to the bronchi and trachea during their discharge, and occasion the inflammatory appearances observed in these parts.

144. *F. The absorption of the contents of cavities* may be inferred when they are found empty, without any manifest communication with bronchi—when this cannot be detected upon dissection, and when the history of the case furnishes no proof of the discharge of these contents during life. I have already alluded to instances of acute phthisis which terminated fatally without expectoration and cough, but preceded by the typhoid symptoms characterizing contamination of the blood by the absorption of morbid matters; and in those the cavities, generally small, were empty, their parietes being soft, or covered by a semi-concrete puriform substance.

145. *G. The healing processes presented by tubercles of the lungs* have been described by ROGET, BOUDET, LAURENCE, BAYLE, BENNETT, ANCELL, and others. HASSE conceives that the cicatrization of tubercles cannot take place if the amount of tubercular deposit be considerable or great, and if the softening be, as it usually is, attended by the continued formation of tubercles. The degree, or the procession, of morbid change in the lungs admitting of remedy cannot be defined, even if both were objects of precise observation. The states of organic nervous power and of the circulating fluids should be viewed as the chief sources, from which the local lesions are to derive reparation. And this end can be attained only by supporting this power, by enabling it to improve the digestive and assimilating processes, and thereby rendering the circulating fluid more vitalized, and less capable of forming or perpetuating the tubercular deposits. Under the influence of this system, and of the improved condition of the blood, morbid products are more sparingly formed; those which are formed have their more fluid parts absorbed; they are consequently atrophied, and their more solid, earthy, or saline parts, as respects tubercles especially, alone remain, either in a passive or inert state, and are increased by subsequent depositions, or exist in such condition as gradually advances their discharge. This is the course usually pursued in the removal of tubercular deposits before cavities are formed, and has thus been termed the process of *cicatrification* (§ 146, 147).

146. *a. As regards the formation of these concretions* it may be inferred that the organic elements of tubercle are absorbed, and carbonate and phosphate of lime deposited in their place; so that the concretions cannot be viewed as the mere solid remains of the pre-existing tubercles. HASSE remarks that the calcareous deposit, in some cases, especially in young subjects, takes

place somewhat rapidly, the outside of the tubercle being then changed into a hard crust, while the central part retains its softness. Occasionally the calcareous matter appears to have been deposited at intervals, producing a series of hard, distinct, superimposed strata. Most frequently when the process advances slowly, the tubercles appear like to moist chalk. Thus the volume of the entire mass continues to diminish, so much so that a considerable portion of lung, as may be inferred from the size of the bronchi leading to it, becomes reduced by obliteration and shrivelling, to a hard shell, holding in its centre a chalky tubercle no bigger than a pea. This healing process is by no means rare, its traces being often found in the lungs of very aged persons who have died of different maladies, and not unfrequently also in much younger subjects.

147. *b. Tubercular cavities heal* in the same manner whether they are connected with several bronchi or shut out from the air-passages. In the latter case exactly the same capsule, resulting from inflammatory induration of the surrounding structure, is found, wherein the enclosed tubercular mass is converted first into a chalky pulp, and ultimately into a *hard calcareous concretion*. The majority of these concretions originate in the small and still closed cavities. They are irregularly shaped, with a granular, rough surface, are hard or friable, and often contain mealy or soft nuclei. They are found most frequently at the summits of the upper and of the lower lobes, firmly impacted within a shrivelled and condensed structure. "In rare instances the residue of tubercular matter, left within the larger cicatrized cavities, is by degrees converted into earthy granules. These are loosely held within the scar-contracted cavity, where they mingle with tubercular and muco-purulent fluids, and may become ejected during a violent fit of cough, provided the implicated bronchial tubes still remain open."—HASSE, &c., p. 340.

148. *c. Cavities cicatrize* in different ways. They may disappear altogether, or contract only to a limited extent. In the former case they are united and filled by a cellulo-fibrous substance. In this case the membranous lining or paries of the cavity becomes thickened by a deposition of plastic exudation or lymph, either upon its external or internal surface, most probably upon the former. The membrane thus grows and contracts towards the centre, until the cavity is filled with a fibro-cellular substance. The gradual obliteration of the cavity is farther effected by the condition of the adjoining parts. If the vomica be near the surface of the lung, the pleura becomes much thickened, and the walls of the thorax sink inward, so as to favour the shrivelling process. The corresponding bronchi are closed, and the healing of the cavity is effected, the remaining scar being either thick, or roundish, or elongated.

149. When the cavities contract only to a limited extent, and simply lose their original characters, their walls are moulded out of the aforesaid layer of shrivelled parenchyma, which now neither contains nor secretes tubercular matter. "These extinct vomicae are frequently seen at the apex of the lungs, and might readily be taken for mere bronchial dilatations, were their real nature not disclosed by the relations of the surrounding pulmonary texture, by the coexistence of cretaceous masses, and, above all, by the character of the membranous lining, which essentially dif-

fers from, and does not immediately unite with, the mucous coat of the bronchial tubes." This internal lining usually adheres firmly to the indurated walls of the cavity, and is either thick, reddened, and velvety, or pale, smooth, and thin.

150. The state of the pulmonary structure, both adjacent and more remote, is influenced by the above healing process; and the consequent changes are well described by HASSE. The inflammatory exudation upon which the above alterations depend often involves the whole of the apex, if not the entire upper lobe of the lung, while the collective bronchial tubes degenerate into white, thread-like ramifications. The involved parenchyma of the lung is now converted into an almost cartilaginous mass, impervious to the air, very scantily supplied with blood-vessels, and presenting, when cut, a smooth glistening surface. Obliterated pulmonary vessels, closed bronchi, cicatrices, and parenchyma infiltrated with plastic materials, are hardly to be distinguished from each other; and the whole adheres firmly, by means of the thickened semi-cartilaginous pleura, to the sunken walls of the chest. A few cretaceous tubercles are still found scattered throughout the hard, nearly homogeneous mass, which, below, merges sometimes gradually, but more often suddenly, into the healthy texture.

151. *d.* The deposition of black pigment into the lungs during the healing process is a very remarkable fact. It is found wanting only, or almost wanting, in the rare instances of the repair of tubercular disease by means of calcareous deposits in youthful subjects. In older persons the black pigment is so constant, and so considerable, that it might be doubtful whether it be the cause, or the sequel, of the cure of phthisis. "Not alone the parts closely adjoining calcareous tubercles and cicatrized cavities, but, in like manner, the entire mass of those extensive indurations of the upper lobe, just described, are found densely loaded with this pigment. Even the moist chalk-like residue of tubercular masses is often so imbued, as to exhibit a slate-gray or a bluish-black tinge." In other cases, where tubercles are more limited, and in young persons, the pulmonary structure is puckered, without induration or extensive obliteration; the cicatrices appearing elongated, the cretaceous residue as isolated granules, and the black pigment uniformly but less densely disseminated in the interstices of the air-cells. The cicatrices are surrounded by emphysema and dilated bronchi, and the thorax is seldom found depressed.

[That pulmonary tuberculosis is often arrested, is now admitted by all pathologists. Dr. BENNETT thinks that this happens in the proportion of from one fourth to one third of all who die after the age of forty. Observations made at the Salpêtrière and Bicêtre Hospitals in Paris, among individuals generally above the age of seventy, showed the proportion in such persons to be respectively one half and four fifths.

The arrestment of tubercular ulceration may take place by the gradual transformation of the exudation into cretaceous and calcareous concretions; by expectoration and absorption of the exudation, the collapse of the ulcerated walls, and formation of a cicatrix; or, lastly, by the ulcerated walls becoming covered with a smooth membrane, remaining open, and constituting chronic cavities, which have occasionally been mistaken for dilated bronchi. All these modes of arrest-

ment may be detected in the same lung, thus causing great diversities of appearance in the pulmonary texture. Increased density of the pulmonary tissue, in the neighbourhood of the cretaceous concretions and cicatrices, is often occasioned by black carbonaceous deposits, and this density and contraction is a frequent cause of pulmonary emphysema in the air-vesicles, as shown by Dr. GAIRDNER. This result leads to dyspnoea, so often observed after the removal of pulmonary tubercle. Whether the occurrence of emphysema, in such cases, exerts any curative power, as suggested by RAMADGE, is by no means established. The most important fact yet known in regard to the disease is, that, if we can check farther tubercular exudation, and keep up the strength and nutritive processes of the economy, such tubercular exudations as have occurred will be rendered abortive, and even large ulcerations will heal and cicatrize.]

152. *H.* In children the lungs are less the predominant seat of tubercles than other parts, especially the mesenteric and lymphatic glands and the bones. When deposited in the former in excess the tubercles pass through their stages rapidly. In very young children the pulmonary deposits are often latent, death ensuing from the coexistence or supervention of disease of other parts. In those subjects who have died of other maladies, the lungs contain grayish, transparent, semi-fluid granules or tubercles, not confined to the apex, but existing equally in the lower lobes. The bronchial glands are at the same time very tuberculous. BILLARD met with five instances of tubercles of the lungs in new-born children; HUSSON and KENNEDY in the fœtus. I have seen the disease in the lungs of several infants of the age of a few months only. The disease in young children is generally acute, and it usually is of this form up to the age of seven or eight years. In young children the tubercular deposits may be as great or even greater in the bronchial, mesenteric, and cervical glands; in the liver, spleen, brain and its membranes, and kidneys, as in the lungs.

153. *I.* The tubercular and other lesions, found in the several organs of adults dead of phthisis, are often very numerous. Many of them have been already described when noticing the complications and intercurrent affections of the disease. In the advanced stages, pleural inflammations occur, productive of every variety of false membrane, of adhesions, of milary tubercles upon the pleura and within the exudations on its surface, and of turbid, reddish, serous, or purulent effusion. When the trachea and larynx are affected, as described above (§ 109), as well as in many other cases, the bronchial glands of the neck and those seated along the trachea are similarly affected, and exhibit all the phases of tubercular disease. The heart is quite devoid of fat in most cases. GLÜGE states that he always found the blood within the larger veins and the heart in phthisis to contain pus-globules, to which circumstance much of the constitutional symptoms may be referred. LOUIS and BIZOT have remarked that the aorta is always more or less contracted. The alterations of the liver and alimentary canal are always remarkable, and described above (§ 114-118). From the searches of LOUIS, MOHR, and HASSE, it would appear that tubercles exist in other organs besides the lungs in the pulmonary phthisis of adults in the following ratio: The

bronchial glands were tuberculous in about one fourth the cases; the mucous membrane of the trachea and larynx in one twentieth only; the cervical glands in the same proportion; the intestinal canal in one half the cases; the mesenteric glands in more than one third; the mucous membrane of the stomach very rarely; the serous membranes very often, and in the following order of frequency: pleura, peritoneum, arachnoid, pericardium. The liver, spleen, urinary organs, brain, spinal cord, are occasionally implicated. The testicles, and the mucous surface of the Fallopian tubes are also sometimes affected. With the exception of the brain and the heart, the absolute density and weight of most organs, more particularly of the lungs, liver, and spleen, are augmented in tubercular phthisis. It therefore follows that the enormous loss in weight sustained by the body, amounting, on an average, to about 50 lbs., is due to the loss of adipose substance.

154. IV. TUBERCULOSIS OF THE BRONCHIAL GLANDS.—*Bronchial Glandular Phthisis*.—The bronchial glands may become tuberculated, either *primarily* or *consecutively*, of similar deposits in the lungs. It is chiefly to the *primary* form of tuberculated bronchial glands that attention is now to be offered. This is almost exclusively a *disease of childhood*. In this primary form, originating in adult or advanced age, bronchial glandular phthisis is comparatively rare; and in the aged it is almost always the more attendant of lingering pulmonary phthisis. Primary tuberculous of the bronchial glands generally commences between the first and second dentition, and finishes its course with the appearance of puberty, although its consequences are sometimes manifest beyond this period. It is obvious that this form of the disease may be associated with tuberculosis of the lungs and of other organs. It may, however, and often does, run its course without any tubercles being deposited in the lungs; or the lungs may become implicated at any period of the glandular malady, and be disorganized with the glands; or, lastly, bronchial glandular phthisis may subside.

155. The course of bronchial glandular phthisis is generally chronic; and the destruction and shrivelling of the affected glands proceed so gradually as to allow the organism time to compensate for the loss. "Hence it readily admits of reparation; nor is it in itself perilous, although accidental circumstances may render it fatal."—Hasse, page 349. The glands at the bifurcation of the bronchi are earliest attacked, and first pass through the several morbid stages. Thence the morbid process generally diverges into three distinct directions: first, to the lymphatic glands following the ramifications of the bronchi into the pulmonary structure; secondly, to those placed between the pericardium and the lungs, and along the œsophagus in the posterior mediastinum; and, thirdly, to those which accompany the large vessels in the anterior mediastinum, and pass from thence to the trachea and the cervical plexus. Only where tubercles are primarily seated in the mesenteric glands do they appear to advance to these glands which follow the course of the œsophagus, passing thence to the cervical plexus. In some instances they probably originate in the glands of the neck.

156. An occasion seldom offers of examining tubercles, in these situations, in their nascent

states. In these states they then appear as gray or yellow granules, up to the size of millet-seeds. In a short time the glands become so infiltrated with tubercles as to form a yellowish-white friable substance, in which no vestige of the former healthy texture is discernible. They thus enlarge remarkably, those at the bifurcation of the trachea often attaining the size of a pigeon's egg, those within the lung that of a hazel-nut, their size decreasing with their remoteness from the part first affected. Though but loosely attached in the midst of cellular tissue in the healthy state, they now coalesce by its medium with the adjoining parts, especially with the bronchi, acquiring from the lardaceously condensed cellular tissue a firm isolating envelope.—Hasse.

157. These glandular enlargements but seldom produce very marked symptoms of compression of nerves or blood-vessels, although important trunks and branches run in their vicinity; but it is not improbable that the little attention hitherto paid to the lesions of the bronchial glands in children has led to the misinterpretation of the symptoms and effects produced by them, and to the disorders actually caused by them being imputed to other sources. It is extremely probable that *spasmodic croup* (see *art. CROUP*, § 13, 14), *Laryngismus stridulus*, and other affections of the trachea and bronchi, are either caused, or aggravated, or perpetuated, by tubercular enlargements of these glands, although nervous filaments and arteries are found, on careful dissection, traversing the localities of, and obviously pressed by, these glands. The veins, however, are more susceptible of pressure by them; but the bronchial canals are seldom much affected by them, owing to the resistance furnished by their cartilaginous rings, and to the more yielding structures adjoining. In some cases, notwithstanding, as shown by ANDRAL, the pressure has acted injuriously on the bronchi; and it may, even in adults, be connected with the pathology of some cases of *asthma*.

158. The tuberculous deposit in the bronchial glands may long continue without much change; but more frequently it undergoes softening. Hasse states that, when the softening proceeds from the centre, one or more small excavations are found containing a purulent and gritty matter, and the process is tedious. When the softening commences at the circumference, the filamentous sheaths of the glands are highly vascular and puffy, constituting at last a mere cyst around the thick, yellowish, tuberculo-purulent fluid. From this period the tumour collapses, its contents either becoming gradually absorbed, or escaping through a passage made by them. Absorption proceeds very slowly, being carried on chiefly by the external vascular coat of the tumour, the inside of which coat has a red velvety appearance. Like a vomica, it generally possesses an unorganized membranous lining, formed of thickened pus and tubercle. The cavity thus produced does not, however, like the pulmonary excavation, continue to enlarge: its walls receive no additional deposition of tubercle, but rather protect from this occurrence; and in no case do two adjacent glands communicate or form one cavity. On the contrary, as the fluid contents are absorbed, the cyst contracts upon the more consistent residue, which, lessening gradually, acquires a cretaceous character, and ultimately is converted into a hard concretion. These products are often met with,

even in youthful persons, in the place of one or other of the bronchial glands, especially at the bifurcation of the trachea.—BECKER.

159. "When the tuberculous mass has remained fluid until long after puberty, or the disease has arisen at a later period, black pigment becomes deposited, both in the unsoftened portion and in the pap-like matter." It is so intimately combined with the latter as ultimately to form a uniform, black, smeary pulp. In such cases, the tumour, while gradually contracting in dimensions, retains the same soft condition for years. Sometimes separate calcareous nuclei are found in the midst of the blackened mass. "This deposition of pigment within glands, totally degenerate and partially destroyed, is the more remarkable as furnishing a proof of connexion with the lymphatic vessels. It can scarcely be reckoned an immediate secretion from the glandular cyst, and necessarily concerned with tubercular eicatrization, because this process in other organs (the lungs excepted), and especially in lymphatic glands, is scarcely attended by any deposition of black pigment."—HASSE.

160. Softened tubercle often escapes by perforating the bronchi, generally from without inward, the tuberculo-purulent fluid bursting through the bronchus. Years are in such a case required for perfect recovery, which is brought about either by the gradual healing of the aperture, while the subjacent gland shrivels away, or by the closing of it ere the contents of the gland are entirely voided, the remainder afterward passing through the several phases, until it undergoes the calcareous change. Sometimes the irritation is renewed at a subsequent period, and the concretions come away.

161. Various other consecutive lesions supervene contingently upon those now mentioned; but these are individually of so rare occurrence as hardly to deserve enumeration. The chief of these are, 1st, the escape of the tuberculated contents of a bronchial gland into the parenchyma of the lung; 2d, perforation into the pleural cavity, where the softened glandular mass is situated immediately under the pleura, at the interlobular divisions (BERTON, RILLIET, and BARTHEZ); 3d, perforation of the œsophagus (BERTON and LABLOND); 4th, simultaneous perforation both of the œsophagus of the trachea and of the pericardium (SYMÉ); and, 5th, perforation of the parietes of one of the large blood-vessels. Of each of these only two or three instances have been recorded.

162. In *children*, in whom alone this disease appears primarily or independently, the lymphatic glands of other parts, especially of the mesentery, often afford the sole evidence of concurrent disease. The lungs are, in particular, sometimes quite free from tubercles. PAPAVOINE states that, of forty-nine children affected with tubercles of the bronchial glands, but thirty-eight had tubercles in the lungs. RILLIET and BARTHEZ never found other organs in children tuberculous without the bronchial glands being pre-eminently so. Still, bronchial glandular phthisis in children often induces acute tubercular disease, the lungs, the liver, the spleen, the kidneys, the serous membranes, &c., being all found, in various degrees and frequency, to contain recent tubercles. In *adults*, on the contrary, in whom either recent, or the remains of former, bronchial glandular phthisis may be discovered, tubercular disease of the

lungs always predominates, and is in itself fatal.—HASSE.

[The usual physical signs of this form of tuberculous are, feeble respiratory murmur on one side, from pressure of one or more swollen glands on the bronchial tubes, dullness on percussion in the interseapular regions, bronchial respiration, mucous râles, and perhaps gurgling. If the rational signs of phthisis, as persistent cough, emaciation, &c., are present, while the physical signs are absent, over the chest, except at the parts above named, we may venture to pronounce the disease to be bronchial phthisis.]

163. V. DURATION OF TUBERCULAR CONSUMPTION.—It is not improbable that tubercles may exist in the lungs of a person hereditarily or constitutionally predisposed to phthisis, from an early age, in a quiescent state, or without advancing to the stage of softening, without shortening by many years the duration of life. This is more likely to occur when the determining causes of the disease have either been avoided or have not acted with much intensity. Instances have come under my own observation that have been characterized by the chief symptoms of the first stage, and by occasional attacks of hæmoptysis, from an early period of life, and yet they reached to upward of 60, and in two cases to 68 and 69 years. I have no recollection of an instance of 70 having been passed in such circumstances; but Dr. GREGORY mentions a case of a person who was consumptive from 18, and died of the disease at 72 years of age. Phthisis, with the few exceptions arising from the occurrence of acute stages of the disease, is essentially chronic or protracted. In general its duration is much shorter in hospitals, and wards containing a number of cases of the disease, and in crowded workshops and manufactories, &c. In 215 fatal cases at the Hospital for Consumption, in 193 cases observed by LOUIS, and in 200 noted by BAYLE, the duration was as follows:

Duration.	Hospital.	Louis.	Bayle.
Less than a month . . . .	..	1	1
In one month . . . . .	..	3	1
From 1 to 3 months . . .	1	11	14
" 3 to 6 months . . .	22	52	44
" 6 to 12 months . . .	66	62	64
" 12 to 18 months . . .	34	24	30
" 18 to 24 months . . .	22	17	18
" 2 years to 3 years . .	29		
" 3 years to 4 years . .	13		
" 4 years upward . . .	14		
" 2 years to 8 years . .	..	23	18
" 8 years to 20 years . .	..	..	10
Doubtful . . . . .	14		

Although tubercles in an early stage may long remain latent or quiescent, yet when they begin to soften, there is every reason to suppose that their advancement is progressive, although at varying rates, or even so slow as to be nearly stationary. It is manifest that numerous circumstances after the commencement of phthisis must tend to accelerate its progress on the one hand, or to retard or arrest its course on the other. The continued or occasional operation of any of the causes of the malady—seasons, weather, climate, age, sex, constitution of the patient, medical treatment, diet, and regimen, may operate in either way. In the Hospital for Consumption it was observed that of those who died within 18 months 60.5 per cent. were males, but only 50 per cent.

were females; while of those who lived beyond eighteen months, 31.9 per cent. were males, but 45.5 per cent. were females. According to the tables of LOUIS and BAYLE, the duration of the disease was twenty-three months, which nearly agrees with M. ANDRAL's experience at La Charité. Sir J. CLARK remarks that in the upper ranks of society, where patients have all the advantages of the best regimen, of change of air, and of medical treatment, the average duration of phthisis is probably not much short of three years.

164. VI. THE PROGNOSIS OF PHTHISIS.—The result in most of the cases of consumption will become apparent from what has been already adduced.—1. The slower the pulse, and the less acceleration remarked in it by change of posture, cough, and mental excitement, the more favourable may be the opinion formed of the duration, if not of the ultimate issue, of the disease. The absence of the flocculent and puriform characters of the sputa in the advanced stages, and of the symptoms and signs of pneumonia, pulmonary congestion, pleurisy, &c.; an increase of flesh, strength, and weight, or even the arrest of progressive emaciation; the non-appearance of night or morning sweats or diarrhœa; the respiration remaining only moderately accelerated, or not being accelerated in a much greater ratio than the pulse; the absence of marked anæmia, emaciation, and debility, and of the other complications besides those just mentioned; the persistence of accustomed discharges, and the continuance in females of the catamenia in the natural or accustomed state; the tolerably regular discharge of the several secreting and excreting functions, especially those of the bowels; quiet repose during night; a mild form of the hectic fever, and an improvement in one or more of the chief symptoms and signs of the malady, may severally or all be viewed as indications of a slow or protracted, if not a curable state of the disease.

165. *B. Much less favourable*, and indeed most commonly *unfavourable*, are the following: Rapidity, softness, and smallness of the pulse, or a pulse ranging about or above 110 in the adult; quickness of respiration above the ratio which the respiration bears in frequency to the pulse; the states of the sputum indicating the second or third stages of the disease; the appearance of aphthæ on the tongue or mouth, or the symptoms or signs of any of the chief complications described above (§ 104, *et seq.*); the occurrence of profuse sweats or diarrhœa, without any obvious cause; inability to lie on either side; great emaciation, or the production of bed-sores; manifest anæmia conjoined with great rapidity and smallness of pulse; great dyspnœa and oppression throughout the thorax; suppression of accustomed or natural discharges or evacuations; a clubbed and fusiform state of the fingers, and incurvation of the nails; loss of the hair, with profuse perspiration from the scalp, neck, and chest; pain and constriction extending between the sternum and spine; the occurrence of a wandering delirium during the febrile exacerbation of the evening and night; and the loss of appetite for food, are the chief indications of a progressively fatal state of the disease.

166. The hæmoptysis so frequently indicating the commencement and progress of phthisis, as well as being an important complication, may, according to its character and amount, be either a favourable or unfavourable occurrence. If it

be an early or incipient occurrence, the pulse being neither very frequent nor small; if the pulse fall in frequency, and if oppression in the chest and difficulty of breathing be diminished by it; if it be of a moderate amount, or even if it be very abundant, and be followed by an amelioration of the symptoms, it may prove even beneficial, by removing pulmonary congestion and incipient inflammatory action, although the presence of a portion of the blood in some of the bronchi may excite inflammatory irritation of their mucous surface. When, however, the hæmoptysis is very scanty, or merely streaks the expectoration, or if it be brownish, rusty, or black, and at the same time scanty or very moderate, it then may be viewed as an unfavourable circumstance, or as indicative of active congestion, or of congestive pneumonia of a portion of lung; if it be abundant, protracted, and the blood very dark and gelatinous, no relief of the oppression and dyspnœa following it; and if, in either case, the pulse becomes even more frequent and the respiration more rapid, the danger is great. In a case of this last description, which I saw a few years ago at Lowestoft with Mr. WORTHINGTON, an arrest of the hæmorrhage was procured by means of the oil of turpentine, and the recovery became complete under the treatment advised in the sequel. Hæmoptysis at an advanced period of the disease, more especially when cavities are formed in the lungs and the loss of blood large, is always an alarming symptom. The same opinion should be formed if the expectoration be a sanious, ichorous, or offensive character, or if it contain shreds or small pieces or patches of disorganized substance or tissue.

167. The existence of cavities, although clearly indicated by all the usual physical signs, is not a sufficient reason for viewing the disease beyond amelioration or even cure, if the pulse and respiration be not greatly accelerated, and the other symptoms be not unfavourable, and especially if the flesh and strength of the patient be not very much reduced; for one or even more cavities may exist in the lungs, and still sufficient healthy structure may remain to perform the functions of respiration, provided that these functions be not too heavily taxed, and that the remaining lungs be not the seat of inflammatory action or congestion, or of tubercular deposit. The falling in and immobility of the parietes of the chest, with great acceleration of the respiration and pulse, difficult respiration, sweats, diarrhœa, and aphthæ are in such cases the indications of a not far remote dissolution. If the patient, not having retrograded during winter or spring, experiences an aggravation of all the symptoms upon the sudden occurrence of warm or hot weather, it may be inferred that no amelioration can be expected; for I have observed that patients thus affected by the transition to a range of temperature of about 70° or upward, generally do not survive above a very few months; and that those who are improperly sent to a warm climate at an advanced stage, soon have their existence terminated by the injudicious change.

168. VII. THE CAUSES OF TUBERCULAR PHTHISIS may be supposed to be fully ascertained, and their influence in producing the prevalent and fatal malady duly estimated, individually and concurrently, by the numerous writers who have treated of its forms and symptoms; yet have these causes been often imperfectly ascertained,

or incorrectly imputed, in respect of certain states of the disease, and their sources, nature, and co-operation very insufficiently investigated. Hereditary predisposition is fully admitted, but the other remote or predisposing causes, which appertain especially to the parent or parents, and influence the organization of the offspring, are insufficiently recognised. The predisposition, also, which is generated, and the more direct effects produced in the frame by the causes which depress the vital influence—whether mental or physical—whether morally or corporeally exhausting, in circumstances peculiar to the individual, by the removal of agents to which the frame has become habituated, or which are necessary to health, and by the action of other agencies, which are either obscure or concealed, or are merely concurrent in their operations with more prominent or commonly admitted causes, are often overlooked or not known; and thus the advantages connected with their prevention and removal are altogether lost. Hence, these *causes* being unknown or unsuspected, their *effects* cannot be prevented; and the means necessary to the removal of the former or the cure of the latter are either altogether neglected, or employed accidentally, empirically, and often inappropriately.

[If the mortality produced by pulmonary phthisis is ever to be lessened in any great degree, it will doubtless be effected by *preventive measures*. These means, when known and appreciated by the community, will be adopted to a greater or less extent, and by their adoption a vast amount of human suffering and human life will be saved. The causes of this disease, as stated by our author, have never been accurately ascertained, for the want of an extensive series of systematic, uniform, and exact observations of the external

circumstances, atmospheric, local, and personal, occurring in each case. We would respectfully suggest to the *Am. Med. Association* the expediency of making a united and energetic effort, throughout every state in the Union, to obtain such observations, as well as the annual mortality from the disease in every state, with a view to arrive at a more accurate knowledge of its predisposing and exciting causes. To this end, a form of a uniform register of cases, embracing all questions calculated to throw any light upon the causation of the disease, should be prepared and placed in the hands of every qualified physician in the United States, and the results which would thus be accumulated in the course of a few years would undoubtedly lead to discoveries of the highest importance. For example, 3000 cases of tubercular consumption annually occur in the single state of Massachusetts, and an equal proportion in all the New England States. Suppose we had an accurate history of all the circumstances attending each of these cases reduced to a tabular form, and easy of consultation, can any one doubt that we should be better prepared to adopt preventive measures in regard to the disease?]

169. When treating of SCROFULA AND TUBERCLES (§ 13, *et seq.*), the *causes of these generic states of the disease* were then fully described; but the *causes* which, whether acting singly or in combination, develop *this species of malady* require attention, more particularly with reference to their modes of action. Certain of these causes, however, which have been fully considered in the article now referred to, will hardly be noticed, or noticed only with reference to this specific disease; while others will receive that attention which their importance demands, with due regard not merely of the *causation*, but also of the *prevention* of this malady.\*

#### CLASSIFICATION OF THE CAUSES OF TUBERCULAR CONSUMPTION.

##### I. THE CAUSES APPERTAINING TO ONE OR BOTH PARENTS.

- A. *Hereditary Constitution, or Predisposition.*
  - a. Transmission to the fetus, or infant.
  - b. Extent of hereditary transmission.
- B. *Diseases of the Parents productive of tubercular Consumption.*
  - a. A syphilitic cachexia.
  - b. A constitution impaired by mercurial courses.
  - c. Exhaustion of vital power, or debility caused by excessive sexual indulgences, or by masturbation.
  - d. A gouty diathesis.
- C. *The Ages and the Social Condition of the Parents.*
  - a. Premature congress in respect of either parent.
  - b. Far-advanced age, especially of the male parent.
  - c. Influences of circumcision or uncircumcision.
  - d. Inter-marriages.
  - e. The occupation of the parents.
- D. *The Modes of Living of the Parents in respect of Food and Drinks.*
  - a. Insufficient or unwholesome food—pork, bacon, &c.; blood and viscera of animals, &c.
  - b. A vegetable and animal diet considered; fish, &c.
  - c. Intemperance, and addiction to spirits—in the male, in the female.
  - d. Causes acting on the female during gestation and lactation.

##### II. CAUSES ACTING CHIEFLY DURING EARLY LIFE, OR PREVIOUSLY TO PUBERTY.

- A. *Inappropriate Food, Drink, and Regimen of Infants and Children.*
  - a. During infancy. The milk of strumous or phthisical nurses.
  - b. Insufficient or unwholesome food in childhood.
  - c. Sleeping with the aged, debilitated, or phthisical.
- B. *Contaminated, cold, and humid States of the Air.*
  - a. Overcrowding, congregating, or sleeping in great numbers, in a close apartment, &c.
  - b. Exhalations from privies, cesspools, drains, or from swamps, &c. [local.]
  - c. Emanations from the lungs and skin of the phthisical.

##### C. *Employments, Exercises, Amusements, and Regimen, previously to Puberty.*

- a. Sedentary employments, irksome occupations, &c.
- b. Deprivation of out-door exercises and amusements.
- c. The congregation of numbers in factories, rooms, houses, and sleeping apartments.
- d. Dress, day and night clothing.
- e. The influence of light, sunshine, and temperature, especially the deprivation of these.
- f. The influence of low temperature, humidity, and exhalations, &c., during sleep; sleeping apartments, &c.

##### III. CAUSES MOST FREQUENTLY ACTING DURING AND SUBSEQUENTLY TO PUBERTY.

- A. *Amusements, Exercises, Occupations, Clothing.*
  - a. Studies, amusements, and exercises, in both sexes.
  - b. Positions of the trunk of the body, supports, stays.
  - c. Clothing in respect of the several regions of the body.
- B. *Trades, Employments, and Conditions of Life.*
  - a. Trades which are injurious by preventing exercise in the open air.
  - b. Occupations in which dust, or other irritating matters are inhaled—grinders, sculptors, &c.
  - c. Occupations which are exposed to great vicissitudes of temperature and weather.
- C. *The instinctive Desires and Emotions.*
  - a. Premature or excessive sexual indulgence.
  - b. The vice of masturbation.
  - c. Celibacy.
- D. *Mental Exertions and Affections.*
  - a. Intense or prolonged mental exertion.
  - b. The depressing mental emotions and affections.
  - c. Nostalgia.
  - d. Prolonged anxiety. Disappointed hopes and affections.

##### IV. CAUSES CONSISTING OF CONTINGENT OR ASSOCIATED INFLUENCES OR CIRCUMSTANCES.

- A. *Sex, Age, Diathesis, and Temperament.*
  - a. Sex, age, &c.

170. i. THE CAUSES APPERTAINING TO ONE OR BOTH PARENTS.—A. *The hereditary transmission of phthisis* is proved, 1st. By the frequency of the disease in the offspring of parents of a scrofulous diathesis or taint, whether quiescent or manifested by internal or external tuberculosis; 2d. By the presence of tubercles in the fœtus, and in infants of tuberculous, phthisical, or scrofulous parents; 3d. By the existence of tubercular consumption in the offspring of a scrofulous mother or scrofulous father, and the scrofulous parent having died, the children of a parent of a sound constitution, in cases of a second marriage, having been exempt; 4th. By the occurrence of the malady in a family in which no other cause exists; 5th. By the hereditary transmission of the disease in the lower animals. DELAFOND states that a phthisical ram produced the disease in from sixteen to twenty sheep.

171. Phthisis may be transmitted to the offspring: 1st. As a predisposition, or proclivity, or diathesis, or taint—terms which are nearly synonymous; 2d. As a latent germ, which may be quiescent for many months or years; 3d. In a more or less developed state in the fœtus. The scrofulous taint of the parent, although quiescent, may give rise either to external scrofula or to internal tuberculosis in the lungs, or in some other organ, or in several organs or tissues, especially in children and young subjects. External scrofula, or external glands which have fully suppurated, is less likely to be followed by phthisis than the quiescent scrofulous taint; but either condition will transmit phthisis to the offspring. The transmission may not take place in the children, and yet appear in the grandchildren. The predisposition, arising either from the scrofulous taint or from declared tubercular disease of some organ or tissue, may remain dormant through life,

not having been roused by the exciting and determining causes into activity, or developed in the form either of glandular enlargement, &c., or of tubercular consumption, so that it cannot be inferred that the offspring of a scrofulous or phthisical parent or parents, who has not been affected with either scrofula or phthisis is, therefore, free from the constitutional taint, or, in other words, from the hereditary predisposition. It is manifest, however, and it will appear still more manifest hereafter, that a very varying proportion of those attacked with phthisis in any community or climate shall have been thus afflicted from hereditary predisposition, numerous other predisposing and exciting causes being sufficient to develop the malady in those not hereditarily or even constitutionally liable to the malady.

172. a. As to the proportion of cases of phthisis that may be referred to hereditary taint, authors differ widely. RUYSCH says that four fifths are hereditary; M. PORTAL, two thirds; MR. ANCELL, one third; M. PIGRY, one fourth; BRIQUET, 36 out of 90; RUFZ, 24 out of 35. MR. ANCELL states that in the Consumptive Hospital 24½ per cent. of consumptive patients were born of phthisical parents. M. ROCHE considers that the children of phthisical parents are doomed to the disease, and such may be the case if they be subjected to one or more of the causes which occur previously to, or during puberty and early manhood. M. LUGOL states that more than half the subjects of tuberculosis have consumptive progenitors. Of 141 persons affected with scrofulous glands, whose family history was investigated by DR. BALMAN, the following accounts were furnished:

The <i>Fathers</i> died of phthisis in.....	9
One or more deaths occurred from phthisis in the families of uncles and aunts on the father's side of.....	61
Grandfathers on the father's side died of phthisis.....	11
Grandmothers on this side.....	17
	98
The <i>Mothers</i> died of phthisis of.....	11
One or more deaths from phthisis in the families of uncles and aunts on the mother's side of.....	38
Grandfathers on this side died of phthisis .	9
Grandmothers .....	20
	78

173. In 30 of the 141 scrofulous persons, no death from phthisis in either parents or collateral relations were ascertained; but whether the latter exhibited signs of tuberculous taint or disease does not appear. In the Hospital for Consumption, of 669 males, 122, or 18.2 per cent.; and of 341 females, 124, or 36.3 per cent., were pre-disposed by the disease having existed in a parent or parents.

174. b. As to the relative frequency of the transmission of phthisis in the two sexes opinions are opposite, and statistical information is very imperfect. J. P. FRANK, J. FRANK, M. BRIQUET, RICHARD, and PHILLIPS, favour the more frequent transmission by the father, while HASSE and others entertain an opposite opinion. From the report of the Hospital for Consumption it would appear that, omitting those cases in which both parents were consumptive, the father transmitted

- b. Diathesis and temperament.
- B. *Seasons and Atmospheric Conditions.*
  - a. Humidity, dryness, temperature, and other atmospheric conditions.
  - b. The seasons—winter, spring, summer, and autumn.
- C. *Climate and Locality.*
  - a. Climate and locality of various countries.
  - b. Climate in connexion with modes of living.
  - c. Climate in connexion with religious and social observances.
  - d. Prevalence in England, London, &c.
- D. *Influence of Confinement in Prisons, Workhouses, and of Expatriation.*
  - a. Prisons, hulks, &c.
  - b. Workhouses, &c.
  - c. Expatriation, &c.
- E. *Vicissitudes of Fortune, &c.*
  - a. Poverty and distress.
  - b. Loss of reputation, of friends, &c.
- V. *PATHOLOGICAL CAUSES OF PHTHISIS.*
  - A. *Previous Diseases of the respiratory and circulating Organs.*
    - a. Catarrh, catarrhal fever, influenza.
    - b. Bronchitis, pneumonia, broncho-pneumonia.
    - c. Hooping-cough.
    - d. Vascular lesions of the heart, with or without hæmoptysis.
  - B. *Exanthematous Diseases.*
    - a. Vaccination, small-pox, &c.
    - b. Measles, scarlet-fever, &c.
  - C. *Suppressed or excessive Secretion and Excretion.*
    - a. Suppression of the cutaneous excretions.
    - b. Excessive secretion or excretion—prolonged suckling.
    - c. Disordered, suppressed, or excessive catamenia.
  - D. *State of organic, nervous, or vital Power.*
    - a. Hereditary debility.
    - b. Acquired debility.
  - E. *Morbid State of the Blood.*
    - a. Anæmia.
    - b. Chlorosis.
    - c. State of the hæmato globulin.

the disease to sons in 59.4 per cent., and to daughters in 43.5 per cent.; and that the mother transmitted the malady to daughters in 56.5 per cent., and to sons in 40.6 per cent. The numbers from which the above results are calculated are, however, insufficient to be relied upon; nor can the facts be determined with precision, especially as respects the absence of any taint in either parent. In a few cases in which I observed with care the constitution of both parents, the taint existing only in one parent, was communicated in very nearly an equal ratio to both sexes of the offspring.

175. *c.* The question may be asked, *In what manner or way is the hereditary predisposition transmitted?* Is it by the general organization or constitutional formation, or by the blood, or by miliary germs? But previously to the consideration of this topic, it may be asked, Is the tubercular taint, either quiescent or manifested by internal or external tuberculosis, necessarily transmitted from parent to offspring? That it is thus transmitted when both parents are predisposed or tainted, cannot be doubted. The taint may be latent, not having been developed into active disease owing to the inefficiency of the exciting causes. When, however, one parent only is thus tainted, all, or only some, or even none, of the offspring may be predisposed, the taint being limited to one or more, or extended, in various grades, to several or to all. That the constitutional taint may exist in the offspring in the form of *miliary germs* is possible, inasmuch as several observers as well as myself have detected these germs in the fœtus where the taint has been manifested in either or in both parents; but this cannot therefore be considered as the usual manner in which the evil is transmitted. It has been supposed to be always conveyed in the blood—the taint existing in the blood of the fœtus and of the individual into which the fœtus is developed in all the stages of growth and existence. This supposition may be correct, but various considerations militate against it. 1st. There is no proof, either chemical or microscopic, of the fact. 2d. The predisposition or taint being permanent, it cannot be inferred as always existing in the blood, which is continually undergoing changes by the functions of secretion, nutrition, and excretion—by the processes of assimilation and of waste—by the metamorphosis of the globules from the states of those existing in the chyle, through those forming the red blood, to their final extinction by the secreting and excreting organs. 3d. If it exist in the blood, it must necessarily vary with the changes and constitution of the blood, or even be eliminated from the blood, during the processes just referred to, or by the agents often passing into and affecting the circulation, or in the course of diseases which sensibly alter the states of the blood; but no diminution or alteration of this taint has ever been produced in consequence of any or of all these agencies. That this predisposition or taint is one not existing primarily in the fluids, although more or less manifestly affecting these fluids, both the circulating and the secreted, may therefore be inferred; and that it is present in those parts of the solids upon which digestion, assimilation, and nutrition mainly depend, must necessarily appear as a rational conclusion—that it is as much a part of the constitutional conformation—of the intimate organization of the tissues and organs, as of the conditions and contour of

the several parts and features of the individual, and of the states of intellectual and moral development and power.

176. *B.* *The disorders of the parents predisposing to tubercular consumption in the offspring* are chiefly the scrofulous taint; the syphilitic cachexia; a constitution impaired by mercurial courses, or by excessive doses of mercury; exhaustion of vital power, or the debility caused by age, sickness, excessive sexual indulgences, or by masturbation; and a gouty diathesis. Certain of these have been fully discussed when treating of SCROFULA and TUBERCLES (§ 23, *et seq.*); and the dependence of phthisis upon the scrofulous taint fully insisted upon, as regards a very large proportion of the cases, both under that head and above (§ 170–175). Others of these sources of predisposition require merely a few remarks at this place. Excessive sexual indulgences, and more especially masturbation, particularly as regards the male parent, have a very marked influence upon the constitution of the offspring, if indeed any offspring be produced by persons thus exhausted. In most instances, the children of these parents are puny, very generally tuberculosed, the membranes of the brain, the substance of the lungs, and other organs being often the seats of the tubercular deposits to an extent incompatible with the duration of life for any number of years or even of months; or if the effects are not so severely and early manifested, a predisposition is at least communicated to the offspring to external scrofula, in childhood or about the period of puberty, or to pulmonary tubercles about the same epochs or at later ages.

177. *a.* *The ages and social conditions of the parents* are not without influence in favouring a predisposition to phthisis in the offspring. Among the most important of these are premature sexual congress, in respect of either or both parents, and far-advanced age, especially of the male parent. The effects upon the offspring are, in all respects, the same as those just enumerated; namely, a very early mortality from internal and external tuberculosis, and a predisposition to tubercular phthisis at early or advanced epochs of existence.

178. *b.* *The influences of circumcision and of uncircumcision*, the former as tending to prevent, the latter as favouring, a predisposition to the scrofulous taint, have hitherto been entirely overlooked; or if any attention, even the least, have ever been directed to the matter, it has certainly been by no means adequate to its importance, as respects the constitutional and mental powers of the offspring. The subject has hitherto been viewed entirely as a religious rite, altogether superseded by the doctrines of Christianity; but unjustly superseded by the earliest schismatics in the Christian Church—by some of the apostles themselves. Circumcision, however, as practised by the followers of MOHAMMED, is very different from that inculcated by ABRAHAM. By the latter, the whole of the prepuce was directed to be extirpated at a period of life most proper for the operation; while the former resorted merely to an incision. The advantages of the Jewish rite are not merely those which have usually been imputed to it; namely, the prevention of the usual effects of the retention of the follicular secretion under the prepuce; but chiefly the prevention of that excitement to masturbation about the period of puberty, experienced by, and so frequent among, the uncircumcised, especially in warm countries; and

the more prolonged act of sexual congress, and the more complete as respects the female, than in persons otherwise circumstanced. The general results in connexion with other predisposing causes influencing the constitution of both parent and offspring, notwithstanding several powerful counteracting circumstances, are more prolific marriages, and the less frequent occurrence of the scrofulous, phthisical, and gouty constitutions, in the Jewish than in other races.\*

179. *c. On intermarriages, or marrying in and in, among particular races, families, and religious sects, &c.* I have already offered some remarks, when treating of SCROFULA AND TUBERCLES (§ 27), showing the unfavourable influence this cause exerts on the offspring. As to the influence which the several professions and occupations of life followed by the parents may exert on the health of the offspring, it is most difficult to arrive at a conclusion, as statistics can furnish no precise data. Whatever injurious effect may be produced is certainly manifested in the guise of tuberculosis, in one or other of its forms and seats. The only inference which can be drawn with justice from the professions and employments of the parents is, that such as are most conducive to the promotion of health and strength will be most likely to favour corresponding effects in their children.

180. *C. The modes of living of the parents as to food, drink, &c., have been too generally disregarded in our speculations on the causes of the disorders and diseases of childhood, and of the constitutional powers and predispositions of the offspring.*—*a.* The injurious effects of insufficient and unwholesome food, and of the frequent use of pork and pork meats, and of the blood and viscera of animals—not only on the parent, but also on the offspring; and the respective influences of a vegetable and an animal diet, were considered when treating of SCROFULA AND TUBERCLES (§ 31, *et seq.*). To these topics I need not revert; but the use of fish, or a purely fish diet, including shell-fish, has not been satisfactorily investigated. In the Shetland Isles, where I resided up to the age of sixteen, and visited for short periods for several years afterward, the labouring classes live chiefly, or rather entirely, on fish, potatoes, meal, and cabbages—the kinds of fish being the most wholesome and best—the cod, ling, the torsk, halibut, haddock, whiting, skate, coal-fish, &c.; and these are very generally taken with the oil of the recent livers as the only sauce. Those who live in this manner are healthy, enduring, and but little subject to visceral disease. Shell-fish is more productive of cutaneous affections than the fish now mentioned; and the former is more fre-

quently followed by other injurious effects, especially in persons of a peculiar idiosyncrasy. (See *art. Poisons*, § 428, *et seq.*)

181. *b.* There can be little doubt of the injurious influence of the intemperance of the parents on their offspring; and there is as little doubt that the injurious effects are mainly evinced by the scrofulous diathesis thereby generated in the children, and developed either into external and internal tuberculosis in infancy, or into tubercular consumption in early or late epochs of existence. It is difficult to say in what sex or parent this vice is most productive of these maladies in the offspring. It is, however, evident that the female who addicts herself to the abuse of intoxicating liquors, and especially during pregnancy and lactation—and there are many both in the middle and lower classes who thus devote themselves and their infants to perdition—will bear an unhealthy fœtus, or one which will be imbued with the diathesis and seeds of disease just mentioned; and, if it live so long, will communicate a similar evil to its offspring. How efficiently are our legislators providing the incentives to the destruction of health, constitution, and morals, in the licenses and encouragements furnished throughout the kingdom to the abuse of intoxicating liquors! But what are these important matters to the higher consideration, to them, of aristocratic interest, family patronage, and the influence of party?

[It has been maintained by some writers that the habitual use of alcoholic liquors serves as a prophylactic against attacks of tubercular phthisis. This may be so, and yet the lungs are very frequently the seat of disease in intemperate subjects. Of 73 intemperate persons who died suddenly, 42 by drowning, and the rest from accident or suicide, Dr. Oeston, of England, found abnormal appearances within the cranium in 65 cases (89 per cent.), and in the respiratory organs in 41 cases (56 per cent.); while in 41 per cent. there were marks of disease in the pericardium, heart, or aorta; in 27 per cent., in the stomach; 10 per cent. in the intestines; 41 per cent. in the liver; in the kidneys, 34 per cent.; abdomen, 73 per cent.; in the spleen, 14 cases: of course several organs were affected in the same individual. We have supposed that there was no exception to the general law that all causes which tend to lower the vital forces, or to derange the digestive organs, predispose, in the same degree, to tubercular disease. With regard to the action of alcohol, LIEBIG supposes that its elements combine with oxygen in the body—that its carbon and hydrogen are given off as carbonic acid and water—the oxygen existing in a free state in arterial blood. It is evident that if the power of the elements of alcohol to combine with oxygen were not greater than that of compounds formed by the change of matter, or that of the substance of the living tissues, they could not combine with oxygen in the body. Thus, by the use of alcohol, a limit must rapidly be put to the change of matter in certain parts of the body: the oxygen of the arterial blood, which, in the absence of alcohol, would have combined with the matter of the tissues, or with that formed by the metamorphosis of these tissues, now combines with the elements of alcohol, and the arterial blood becomes venous without the substance of the muscles having taken any share in the transformation. The amount of carbonic acid given off by the lungs,

\* [We do not see clearly the connexion between the cause and the effect here pointed out by our author. That there is no nation more addicted to sexual indulgences than the Jews, we suppose will be generally admitted; and they have always borne this character. Polygamy was allowed "for the hardness of their hearts" (Mark, x., 5), notwithstanding circumcision. There is no evidence, moreover, that the Jews are less addicted to masturbation than other nations; and if they are less liable to scrofula than others, we would attribute the exemption rather to the prohibition of pork as an article of diet. Nor can we subscribe to the sentiment, that circumcision was "unjustly superseded by some of the apostles," by the rite of baptism, unless Christianity itself be regarded as an unjust innovation upon the Jewish religion, which no Christian, we suppose, will concede. The hygienic regulations of Moses, apart from circumcision, are well calculated to promote the general health, prevent the occurrence of "scrofulous, phthisical, and gouty" affections, and render marriage "prolific."—*Ed.*]

however, is diminished under the influence of alcohol, while the animal heat is somewhat lowered, and the general strength diminished, or, as LIEBIG says, "weariness, feebleness in the limbs, and drowsiness, plainly show that the force available for mechanical purposes, in other words, the change of matter, has been diminished." If ROKITSKY'S views in regard to the prophylactic power of venous blood against tubercular disease be well founded, it is possible that the use of alcoholic drinks may, in this manner, exert a similar prophylactic power. Observed facts would seem to lend countenance to such a belief. Thus, the late Dr. SWETT, of New York, in his work on "Diseases of the Chest," p. 238, remarks, "Two medical gentlemen, attached to the public dead-house in this city (New York), in which bodies are deposited which are found in the streets, or without friends, discovered, in about 70 post-mortem examinations of those who had died of the most confirmed and aggravated intemperance, not a single case of tuberculous lungs"—a most surprising result, when we remember that this unfortunate class have probably long suffered from poverty, bad nourishment, and exposure to the weather—influences which are regarded as predisposing to the tuberculous deposit. It should, however, have been stated that in a majority of these same cases there were signs of disease in the pulmonary organs, as pneumonitis, chronic catarrh, pleurisy, hydrothorax, &c., as well as in many other important organs, so that, as far as *longevity* is concerned, nothing is gained by the habitual use of alcoholic drinks. No fact is better established than that the average value of human life is vastly greater in those who entirely abstain from such stimulants in health. As a remedy for phthisis, we have no doubt that alcohol, like cod-liver oil, and other hydro-carbonaceous compounds, is often of great service as a calefacient and nutrient, and by preventing the too rapid disintegration and metamorphosis of the tissues.]

182. Other causes besides intemperance may so affect the mother during the child-bearing period of life, and during pregnancy and lactation, as to favour the development of a scrofulous and tubercular disease in the fetus and infant. Too low living, unwholesome meats, especially the too exclusive use of pork and bacon, anxiety of mind, and all the distressing and perturbing emotions, are more or less injurious to the offspring, and in the way just stated, more especially when conjoined with the other causes of ill health, which abound in all cold, low, humid, and ill-drained localities; in crowded and ill-ventilated houses and apartments, and in crowded or close manufacturing and manufacturing towns.

183. *c. The use of tobacco* in any way, either by smoking, snuffing, or chewing, is most injurious, especially in early life, and as respects its effects upon the constitution of the offspring, more particularly when either of these vices are indulged to excess by the male parent. Numerous instances have come before me of young men who have become habitual tobacco-smokers in early life, and who, having married, have either failed of having a progeny, or had children that could not be reared; or, if they reached any of the early epochs of life, were subjects of tuberculosis in one or other of its forms or seats, and especially of tubercular consumption. (See *art. Poisons*, 523, *et seq.*)

184. *ii. THE CAUSES OF TUBERCULAR CONSUMPTION*

THAT ACT CHIEFLY DURING INFANCY, CHILDHOOD, AND EARLY LIFE, OR PREVIOUSLY TO PUBERTY, have been so fully discussed under SCROFULA and TUBERCLES (§ 30-64), that very little is left for me to add at this place. The reader will find the several agencies arranged under this class considered at the place now referred to. There are, however, a few topics thus arranged which require notice, as being of some importance in a prophylactic point of view.—*A. Sleeping with very old and debilitated persons* is certainly prejudicial to the healthy, both in predisposing to tubercular consumption, and determining or developing the disease in those predisposed by a scrofulous diathesis or other influences. It may also be associated with other causes, and the results become more immediate and severe.

185. *B. Infection.—Emanations from the lungs and skin of persons, in the second or third stages of phthisis especially*, are certainly sometimes productive of consumption, more particularly in young persons of a scrofulous diathesis, and in those who are predisposed by other causes, or who are subjected to several concurring influences. The inhalation by the healthy of the emanations from the lungs and skin of the consumptive, and the consequent appearance of the disease in the former, may, as in other cases of infection, be productive of its injurious effects only in the circumstances now stated, but the disease is caused by infection nevertheless, although the fact is stated loosely by many writers as one of the propagation of phthisis by contagion, and denied by others, as, indeed, the infectious nature of nearly every disease has been denied by some, who consider belief in infection to be credulity, and skepticism to be a proof of a "strong-minded" physician, or rather of an incredulous old woman. Although phthisis, in the circumstances favourable to infection, may be communicated to others, especially when the healthy sleep in the same bed or apartment with the sick, and although this result is, perhaps, more likely to occur in persons under or about the period of puberty than at a much more advanced age, yet for many years after puberty the person thus exposed and predisposed may be attacked; and this result is the more likely to take place in the cases of married, especially recently married, persons. I state this as the result of my observation; and, although the matter has been discussed from the days of GALEN, and the occasional transmission of the disease by infection believed by him, by RIVIERUS, MORTON, VAN SWIETEN, NARDUCCI, RONCALLI, CHAVET, J. FRANK, HUFELAND, HILDENBRAND, and many others, and denied by SALMADE, CASTALLANI, PORTAL, and numerous other writers, it still remains in dispute.\*

186. *C. Employments, Exercises, Amusements, and Regimen previously to Puberty.*—Sedentary employments, irksome occupations, and confine-

\* [Occasional facts have been observed, which seem to favour the doctrine of the contagiousness of tuberculosis, but they are rare, and perhaps were only coincidences. LEGAL states that he had observed scrofula under all its forms for 25 years, and yet had been unable to detect a single case of contagion (*On Scrofulous Diseases*. N. Y., 1845, p. 246). We have met with several cases where the wife, from watching over and nursing a sick husband with phthisis, has gradually declined from the same disease; but then it is to be remembered that anxiety, loss of sleep, depraved appetite, want of exercise in the open air, &c., are powerful predisposing causes, and would probably lay the foundation of the disease, independent of contagion. We doubt, therefore, whether phthisis can ever be truly said to be contagious.—*Am. Ed.*]

ment in close or dark apartments, are more or less influential in predisposing to, or more directly occasioning, tubercular phthisis. The deprivation of out-door exercises and amusements, so requisite at this period of life to the development and strength of the constitution, and the congregation and confinement of numbers in ill-ventilated factories, houses, or sleeping-apartments, blight the vital endowments of the frame; and of all the structures and organs, the lungs, like the leaves of a plant—both being the respiratory organs of their respective bodies—are the first to experience, and the most disposed to sustain injury. Nor are dress, night and day clothing, the influence of light, sunshine, and temperature, at this period of life, undeserving attention as respects both sexes; for, although either of these singly may appear of little importance, yet operating, as they often do, in combination, their effects on the general organization are often remarkable. The frequent practice of leaving portions of the body uncovered by the dress, without reference to the weather and season, during the early periods of life—the very low temperature of sleeping-apartments during the winter season, in this and some other countries, while the confinement of the air by closely-drawn curtains around the beds causes the repeated respiration and consequent contamination of the air, thereby inducing feverish, restless, and unrefreshing sleep, and a contaminated state of the blood, are among the most influential occasions of an imperfect development of the body at a period of life when all the aids to health and strength are most especially required. Not infrequently, also, other agencies are brought in co-operation with those just mentioned, and these too of no mean influence. Deprivation of light and sunshine—of the salutary influence of the sun's rays on the frame—not infrequently, especially when aided by the causes already noticed, produces an etiology similar to that occasioned by this cause in plants; and, although the body grows in height, and the vessels extend in the direction of their axes, as in plants, yet the various structures are loosely, weakly, and insufficiently formed, each one being deficient in tone, firmness, and vital cohesion. Associated with this state of imperfect organization, the blood presents a similar defect of assimilation, and an arrested development of the red globules. It is thin, watery, and, although it may abound in colourless globules, or in those not yet metamorphosed into red globules, these last are very much diminished in number, or in their usual proportions. Nor should the mental depression, the irksomeness, the weariness of both body and mind, occasioned by the circumstances noticed under this category, and their effects upon the youthful constitution, be overlooked. These circumstances, when acting either singly, but protractedly, or in various combinations, exert their injurious influence primarily, although not always manifestly, on the lungs. These organs, although generally the first to suffer, are not always the first to indicate disorder. The functions of digestion, assimilation, and nutrition often furnish the earliest indications of disease to the casual or superficial observer, but the experienced eye, and the informed mind, detect the antecedents of these, and carry the analysis of the morbid phenomena much farther, and until the agencies producing them are fully disclosed. (*See SCROFULA and TUBERCLES*, § 39, *et seq.*)

187. iii. CAUSES OPERATING DURING AND SUBSEQUENTLY TO PUBERTY.—A. It is manifest that when the mental *studies* of the upper and middle classes of society, at this period of life, are pursued too far, or to the neglect of those amusements and exercises requisite to health, and to the proper development of the frame, pulmonary consumption will follow in a large proportion of cases, especially when the constitution is predisposed by original conformation, by the strumous diathesis, or by other causes acting in earlier life, or concurrently with this. If these studies are rendered still more injurious by stooping positions, or by pressure of the side against a desk, whereby the actions of the respiratory apparatus are hampered or confined within too narrow limits, the injurious effects will be more certain. But, where these latter causes are not present, others equally injurious may operate; and these may either be too close cinctures of the lower regions of the chest, the pressure of unyielding, or insufficiently yielding supports in the stays worn by females; the use of steel supports, which conduct the electricity of the frame from the body into the air, and thereby deprive the nervous system of a salutary stimulus; and insufficient clothing on the neck, upper regions of the chest, and shoulders, or even the complete exposure of these parts without any clothing whatever, are not without their influence, either as exciting or concurrent causes, especially where a predisposition to this disease already exists. (*See also art. SCROFULA and TUBERCLES*, § 57, *et seq.*)\*

188. B. *Trades, employments, and conditions of life* are conducive to pulmonary consumption when they prevent exercise in the open air; when they are followed in cold, low, close, humid, and dark apartments or situations, or in confined, bent, or cramped positions of the body, as by miners, &c. As to the comparative liability of persons pursuing different trades and occupations, no precise information has been furnished, as the number of persons occupied in each of these trades, in connexion with the number attacked with phthisis, can rarely be obtained. It is manifest, however, from the researches of Drs. GUY and LOMBARD, that the deaths from this disease in those who follow in-door occupations are about double the deaths of those who pursue out-door employments. Shoemakers, tailors, milliners and dressmakers and other needlewomen, clerks and shopmen, weavers and gloves, compositors and printers, servants, bakers, &c., are among the trades most liable to phthisis. BEDDOES stated that

\* [We think that too little importance is attached to the influence of *diet* as a predisposing cause of phthisis. It is a disease characterized by a deficient and depraved nutrition, an impoverished state of the blood, and constitutional debility of the digestive organs, and whether the result of predisposition or otherwise, its foundation is often laid in mal-assimilation of food, or food of an improper kind. This is evident from the fact that the disease may be warded off by measures directed to the invigoration of the digestive organs, such as appropriate diet of nourishing animal food, abounding in hydro-carbonaceous and protein matters, with suitable exercise, and other tonic regimen. DR. CHARLES HOOKER (*Trans. Am. Med. Assn.*, 1855, p. 478) contends that, in most cases of phthisis and of predisposition to it, among other errors of regimen, four are especially prominent, viz.: 1st. Irregular eating; 2d. A restricted variety of food; 3d. The avoidance of oily nutriment; 4th. An excessive use of drinks; and he urges that if due attention were given simply to the correction of these errors, even with no medication, more could be accomplished in the cure and prevention of phthisis than by the most efficient medication, without attention to dietetic regimen.—*Ed.*]

butchers are less liable to this malady than those following any other employment, and later observations have confirmed the statement. Dr. TROTTER made a similar remark in favour of sailors, and this is rendered more obvious by the more liberal diet allotted to them now than formerly. Dr. WITHERING considered stable-boys, grooms, post-boys, and dragoons less liable to phthisis than other employments, and such appears, upon the whole, to be the case. The occupations in which dust and other irritating particles, whether mineral or vegetable, are inhaled into the lungs are especially productive of diseases of these organs, and particularly of pulmonary consumption, bronchitis, asthma, and various complications of these, either with one another or with other lesions. But this subject, and the several topics connected with it, more especially with relation to the causation of pulmonary diseases, are fully considered under the head ARTS and EMPLOYMENTS as Causes of Diseases.

189. *C. The instinctive emotions and desires* are more important causes of tubercular phthisis than is generally supposed by either medical men or others; and this category of causes are most influential in young persons of a scrofulous diathesis, and in those who are otherwise predisposed, more especially by the causes already mentioned.—*a.* Premature or excessive sexual desires and indulgences, and still more the crime of self-pollution, are the chief of the class of causes in producing tubercular phthisis, and several other maladies. This crime, for it is no less than a crime, and one most severely, but not unjustly, punished by the Mosaic law when detected, is one more frequently practised by both sexes than may be believed by those who have not had occasion to inquire into the matter; and it is most prevalent in those who are sanctimonious and pharisaically censorious of others. The injurious effects of this crime are probably greater in the male than in the female, especially in causing tubercular phthisis; and it is not improbable that the rite of circumcision among the Jews was instituted partly with the intention of preventing the excitement to the commission of it that is liable to occur in the uncircumcised. Various mechanical contrivances for the prevention of the vice in females were employed from very early ages, and several of these adopted in the middle ages may be seen in museums of antiquities. No more certain means of exciting females to this vice can be supposed than riding. Instances have come directly to my knowledge of females having relinquished horseback exercise entirely on this account.

190. *b. Celibacy* may be viewed as a cause of tubercular phthisis, although the reason of its being a cause may not be obvious to many. It is, however, more generally known that the average duration of the life of bachelors is much under that of married men. This is mainly owing to the circumstance of their having become addicted to the crime of masturbation. A very large proportion of those who are thus addicted are impotent, and many of them are conscious of this fact, and do not marry; while others continue this vice in preference to sexual congress, and often pay the penalty by inducing this or other diseases. Several instances have occurred in my practice of persons having admitted, when afflicted with phthisis, or with any other of the maladies entailed by this vice, that they were conscious of the cause only when too late, and often

when their minds and the powers of volition were too much weakened to resist the impulse to its commission. Even married men who had become addicted to it previously to marriage have continued it subsequently, as they have themselves confessed to me in several instances.

191. *D Mental Exertion and the moral Emotions.*—*a.* Mental exertion, especially when prolonged or intense, is more frequently a concurring than an exciting cause, unless where an original or acquired predisposition to phthisis already exists. It is injurious chiefly about or soon after the period of puberty, when the frame, in all its parts, is not fully developed and consolidated, and when exercise in the open air, and in light and sunshine, which it often prevents, and which is requisite to perfect bodily organization, is neglected. This cause is often also heightened by the position of the body, especially by the stooping position, which during mental application is often too long retained.

192. *b.* The depressing emotions and affections, anxiety, longings after the objects of affection, either absent or lost, disappointments, losses of fortune or friends, &c., severely depress the organic or vital influence, impair digestion and assimilation, and predispose to, if they do not actually occasion, this malady.—*c.* Under this category may also be placed nostalgia in its various longings for early abodes, scenes, and objects, and for the society of early or beloved friends. (See also *arts. DISEASE, the Causation of*, § 22, *et seq.*, and SCROFULA and TUBERCLES, § 61, 62.)

193. *iv. CONTINGENT AND ASSOCIATED INFLUENCES OR CIRCUMSTANCES AIDING OR CONCURRING IN OCCASIONING PHTHISIS.*—*A. Sex.*—According to the Registrar-General's returns, the deaths during two years and a half (1837, '8, and '9), in England and Wales, from phthisis were 146,338, being 69,009 males, and 77,329 females; and in 1847 the deaths from this disease were 25,083 males, and 28,234 females. Mr. ANCELL says, that "from the Irish reports, it appears that of 135,590 deaths from phthisis, 63,635 were males, and 71,955 females. In London, however, and in the large manufacturing towns, the proportion of deaths from phthisis in males and females was different. In London, from 1843 to 1846, the deaths were greater in males than in females, by nearly six per cent. According to the returns for 1847, the deaths from scrofula, tabes mesenterica, and hydrocephalus were 8105 in males, and 6542 in females; and from phthisis 25,083 males, and 28,234 females; thereby showing that, while the former scrofulous diseases were more fatal in males than in females, the latter, or phthisis, was more fatal in females by nearly six per cent (5.9). In this country, therefore, it appears that females are slightly more liable to consumption than males. In the metropolitan district, however, the deaths in 1838 from phthisis were 4057 males, and 3630 females; and in 1839, 3749 males, and 3355 females. The deaths in this district, in 1838, from phthisis were 7687, while in the southern counties, the population of which is somewhat greater, they were 5805.\*

\* [In the city of Baltimore, for the year 1850, the mortality among the blacks from phthisis was 50 per cent. greater than among the whites—the males being 43.5 per cent., to 56.5 per cent. for the females. If we compare the sexes at different ages, we find that up to 15 years the per centage is the same for both; from 15 to 45, it is 38 per cent. for the males, and 62 per cent. for the females. After this age the males slightly predominate.

194. *B. Age.*—The several tubercular maladies present a greater or less frequency of occurrence at one epoch of life than at another. Tubercular meningitis and hydrocephalus are most frequent during infancy; mesenteric decline in early childhood, or about the period of weaning; external scrofula, from the period of weaning till puberty; and phthisis from puberty until advanced age. The following abstract from the returns for 1845 and 1846 will show the deaths from phthisis, in London, at successive epochs of life:

Years of Age.	Mortality from Phthisis at successive Epochs.			
	Males.		Females.	
	In 1845.	In 1846.	In 1845.	In 1846.
Under 5 years.	354	234	316	269
5-10	88	88	114	92
10-15	59	61	107	104
15-20	191	219	214	228
20-25	343	387	349	362
25-30	405	450	426	434
30-35	436	456	379	383
35-40	431	454	328	401
40-45	379	397	279	305
45-50	312	346	218	211
50-55	240	234	133	135
55-60	155	179	97	99
60-65	111	104	72	60
65-70	73	66	46	48
70-75	21	36	15	15
75-80	9	14	9	6
80-85	4	1	1	3

195. In 1845 the deaths from phthisis in London, at all ages, were 3624 males, and 3107 females; and from all causes, at all ages, 24,496 males, and 23,836 females; the deaths from phthisis being in both sexes 6731, and from all causes 48,332. In 1846 the deaths at all ages from phthisis were 3729 males, and 3161 females; and the deaths from all causes, at all ages, were 24,941 males, and 24,148 females; the deaths from phthisis, in both sexes, being 6890, and from all causes 49,089. From these returns it appears that the proportion of deaths from phthisis among persons advanced in age, the number of persons thus advanced being considered, continues great to very mature age.

196. The following table is an abstract from a more extended one by Mr. ANCELL, which he had made from the Registrar-General's returns for 1847, in which the deaths by phthisis, in all England and Wales at the several epochs of life, are stated and compared with the mortality by all causes, and with the number of persons living of the specified age in the middle of that year.\*

197. *C. Diathesis and temperament* predispose more or less to phthisis, but it is difficult to determine the extent to which they have this effect. It is even more probable, and more agreeable with experience, that original or early-acquired conformation of the body, arising from causes affecting the parents, has more influence in predisposing to phthisis than the temperaments, as they have hitherto been described by physiologists, or

Years of Age.	Mortality from Phthisis.			Mortality from all Causes.			Estim'd Population of that Age in 1847.

85-90	9	10	19	3,487	4,380	7,867	10,770	14,881	25,651
90-95	2	3	5	1,006	1,571	2,577	2,662	4,333	6,995
95 et sup.	....	....	....	302	538	840	622	1,175	1,797
All ages.	25,083	28,340	67,964	113,076	207,901	420,977	8,368,914	8,755,174	17,124,088

The deaths from 15 to 20 were 7.2 per cent.; from 20 to 30, 31.2 per cent.; from 30 to 40, 25 per cent.; from 40 to 50, 12.6 per cent.; from 50 to 60, 10 per cent.; over 60, 6.2 per cent.; from 1 to 15, 6 per cent. The mortality from consumption, as compared to the whole deaths, excluding still-born, in the following cities, is as follows:

Baltimore, average from 1850 to 1854 is	1 in 6.2
Philadelphia, 1854.....	1 in 8.0
New York, 1852 to 1854.....	1 in 7.5
Boston, 1843 to 1852.....	1 in 6.6
London, 1853 & 1854.....	1 in 9.2

(CHARLES FRICK, *American Journal of Medical Science*, Oct. 1855, p. 380.)

\* [It is to be regretted that we have no data by which we may judge with any accuracy in regard to the prevalence of tuberculosis in the different sections of the

United States. It is a common belief that the disease is more rife on the Atlantic coast, especially of New England, than in the interior, and at a distance from the sea-board. The mortuary statistics of Massachusetts, however, taken by the state authorities, do not sustain this opinion—the western counties furnishing as large a ratio of deaths from phthisis as the eastern. There is little doubt that, if a correct comparison were made between an equal population in a malarious district of the western country and on the sea-board, where malaria does not exist, the mortality from this disease would be found far less in the former. But between the Northern and Southern States, provided the regions are not malarious, it is probable that very little difference would be

conventionally admitted by medical writers. Temperaments are so mixed with one another, with diathesis, habit of body, and with states of vascular plethora, or its opposite, as to be rarely distinguished with precision, or to be viewed only as states of constitution, which every physician estimates conformably with his own views, although he may not be able to describe them with precision, or agreeably with the conception of others. I have nothing to add at this place to what I have observed above (§ 9, *et seq.*) on this subject, and that is much less satisfactory to myself than I wish.

193. *D. Seasons, weather, and atmospheric conditions and vicissitudes*, have less direct influence in producing phthisis than has generally been supposed. They are, however, frequent concurrent and determining causes, and when they appear most efficient in occasioning this malady, they often act by producing catarrh, bronchitis, or pneumonia, either of which may develop quiescent phthisis into a state of action, or call the latent predisposition into a more manifest form. Cold conjoined with humidity, especially when the already predisposed, or those not accustomed to these atmospheric conditions, are exposed to them, and sudden vicissitudes of cold, warmth, and humidity, or dryness, or rapid alterations of these, are certainly powerful agents, especially in low situations, in developing phthisis. The rapid transference of terrestrial electricity into the atmosphere, during humid states of the air, has an injurious influence on persons predisposed to, or labouring under phthisis. The vicissitudes of temperature to which many expose themselves by passing from a very warm apartment into the

cold external air, or from the latter into the former, and by sleeping in a chamber the temperature of which is many degrees below that of the apartments used during the day, are certainly more or less injurious to persons disposed to phthisis. In cold sleeping-chambers, although the body is protected by warm bed-clothes, the lungs are exposed either to a low range of temperature, or to a higher range generated by breathing the same air repeatedly in consequence of the confinement of the air by bed-curtains. No small injury is often also produced by over-exciting or overheating the body, so as to produce copious perspiration, which often chills the surface, and throws the momentum of circulation inwardly, favouring pulmonary congestion, especially when the external surface is not protected by flannel next to the skin. Living in damp or ill-drained houses, removing into recently-built houses before the walls are quite dry, and living in those which are built on a humid or clay soil, without sunk areas around them, or without sufficient space for ventilation, are more frequent causes of disease, and especially of pulmonary consumption, than they are generally supposed to be, especially in persons of a scrofulous diathesis, or otherwise predisposed.

199. The influence of *seasons* on phthisis is but slight, and almost undetermined. Medical statistics give very little information on this topic, and that little is deficient in precision. The returns of the Registrar-General furnish no data respecting it, for the deaths from phthisis during the four quarters present little difference as to numbers; and when the very remarkable differences of duration presented by this disease are considered, it cannot be expected that the deaths can be an index to the seasons in which the malady was occasioned.

found in this respect; and so, on the whole, little if any advantage is gained by a change of climate. The Federal census of 1850 purports to furnish the mortality in one year in every state in the Union, as well as the diseases, age, nativity, &c.; but so little care was observed in taking the returns, that they are of little if any value to the statistician. If they are to be believed, then Mississippi is a healthier state than Rhode Island, and Alabama twice as healthy as Massachusetts, and four times as healthy as Texas; while the deaths from consumption in Texas are but half as many as in Louisiana, and only one seventh as many as in Massachusetts, and one fifth as many as in Maine! The following table, compiled from the U. S. Census returns of 1850, may, however, have a certain kind of value, and we therefore give it:

States.	Aggregate Population in 1850.	Total Deaths.	Per Cent.	Total Deaths from Consumption.	Per Cent. of Deaths from Consumption.	Ratio of Deaths from Consumption to whole Population.
Texas.....	212,592	10,057	4.7	112	.05	1,898
Louisiana.....	536,135	11,956	2.2	641	.11	838
Alabama.....	771,623	9,091	1.1	362	.04	2,131
Mississippi.....	606,326	8,721	1.4	332	.05	1,826
Arkansas.....	209,897	3,021	1.4	132	.06	1,590
N. Carolina.....	869,039	10,165	1.1	562	.06	1,540
Tennessee.....	1,002,817	11,875	1.1	879	.08	1,140
Missouri.....	652,044	12,292	1.7	648	.09	1,052
Virginia.....	1,401,661	19,050	1.3	1,616	.11	869
Dis. Columbia.....	51,687	846	1.6	135	.25	582
Maryland.....	583,039	9,621	1.6	1,101	.18	529
Ohio.....	1,800,329	28,957	1.5	2,538	.14	739
New York.....	2,581,847	33,717	1.3	5,372	.20	480
N. York City.....	515,547	11,838	2.2	1,319	.24	390
Massachusetts.....	994,514	19,404	1.9	3,426	.34	290
Maine.....	583,162	7,584	1.3	1,702	.29	362

According to the above table, one in 1895 die in Texas of phthisis, one in 2131 in Alabama, and one in 290 in Massachusetts! So that, as we go north from Alabama, we have the following per centage: .05, .06, .08, .11, .14, .18, .25, .34. This statement is sufficient to show the value of the U. S. Census mortality returns.—*Ed.*

200. *E. Climate and Localities.*—*a.* As to the climate of different countries, and as to the influence of situation and locality, either in favouring or in preventing the prevalence of phthisis, our knowledge is altogether imperfect. Much that has been asserted on this subject is more or less inaccurate, the inaccuracy being often in proportion to the dogmatism with which the matter is treated. That some climates and localities present a much greater prevalence of this disease among their inhabitants than others is an admitted fact; but the degree of prevalence, or the amount of influence attributable to climate only, and the shares which may be imputed to situation, circumstances, habits, customs, &c., of the inhabitants, especially the natives, are either very imperfectly known, or not known at all; even at the best an approximation to the truth only is to be expected. Several writers have stated that pulmonary diseases, and more especially consumption, are rare within the tropics, and in the natives of these countries particularly; but Dr. WEBB states that the "records of cases of natives of every part of India show that phthisis and pulmonic affections are at least not uncommon diseases among natives of India, and only yield in frequency to fever, cholera, and dysentery, presenting every form and variety that is to be met with in any other part of the world." Dr. GREEN states that pulmonary consumption is a prevalent disease in the lower provinces of Bengal; and Dr. WEBB, who quotes this statement, remarks that he has himself "observed the disease extensively among the Hindoo race, and the Puharrees

inhabiting the lower belt of the Himalaya range of mountains." The same writer refers to Dr. GODEVE's report of the prevalence of pulmonary disease in *Upper India*; wherein he states, "tubercular phthisis we have had abundance of, as the detailed autopsies forwarded every month show."—WEBB'S *Pathologia Indica*, p. 100, *et seq.*

201. *b.* Dr. ARCHIBALD SMITH, in some valuable communications he kindly sent me respecting the diseases of *Peru*, remarks, that "In the negro hæmoptysis is less frequent, perhaps, as a symptom of phthisis, than it is of disease of the heart or aneurism of the aorta. Hæmoptysis is also very often observed in the congestive stage of fever in the Peruvian negro; but with the fever the sanguineous sputa disappear. Comparatively speaking, phthisis is decidedly less common in the negro than in the cross between the negro and Peruvian Indian, or pure Indian bred in the mountains, but migrated to the coast. The mixed races with preponderating Spanish type or blood, constituting the creole white race, nurtured in luxury, idleness, and pleasure, and consequently with an unhealthy physical and moral training, are delicate and feeble of organization; and therefore, of all the different races, the most prone to ailments and failing health, and also most subject to tubercular consumption. In the *purely* white race phthisis is comparatively rare, except among such youths as are sent from Europe with pulmonary complaints. But, as these are found in mercantile establishments, they are usually sent from one station to another, without trying the benefit of mountain air; for in the mountains there are few European mercantile establishments. In 1792 Lima contained 52,000 inhabitants, of whom 20,000 were whites, 23,000 of the negro race, 6000 of the cross of white and Indian, and 3000 only of the pure Indian. At that period the races were treated in their respective hospitals. The whole deaths by hospital and parochial returns were 2795 for the year given. From the *white* hospitals 650 dead were buried, while 692 died in the negro and Indian hospitals; thus showing a much greater mortality among the whites in general (including the creoles). Now, rest assured that phthisis always maintained its relative position among the causes of death next to fevers and dysentery. In the Indians on the coast the relative mortality is far beyond that of the negro. In Lima phthisis and intermittent fevers are less common in the negro than in the white and Indian races. But diseases of the liver, of the heart and aorta, and of the gastric and intestinal viscera, especially dysentery, commit more havoc in the negro and other dark members of this family than among the other races."

202. In other parts of *South America* the occurrence of phthisis appears to be infrequent, especially among the unmixed dark races; but the information respecting these parts and races is very defective. In *Mexico* this disease is said to be rare; as respects the city of Mexico, this may be owing to its high position above the level of the sea, and to other circumstances; but no information is furnished as to the comparative immunity of different races in this country. According to Dr. HANCOCK, phthisis is almost unknown on the coast of *British Guiana*, and very rare in the mountains. This immunity must have reference chiefly to the native races, as instances of death from phthisis have occurred among both whites and blacks who have removed to that country.

Col. TULLOCH states that in St. Helena the mortality of the population from diseases of the lungs is about 3·2 per 1000 annually.

203. *c.* Upon reference to my notes respecting the diseases of those parts of the *west coast of Africa* which I visited and resided in for short periods many years ago, and which were inhabited almost entirely by true negro tribes, individuals of the white, Arab, or Moorish races being very few, I find it stated that phthisis, remittent and intermittent fevers, appeared very rarely to occur among the former; but when they migrated to somewhat colder climates, even to the West Indies, phthisis was sometimes observed among them; and this became the most fatal malady to them, excepting small-pox, when they were sent to temperate or cold climates. Although dysentery and chronic diarrhœa were among the most prevalent and fatal maladies among negroes in those parts of Africa, yet the liver appeared less frequently diseased than the spleen in this race; and much less so than in the purely white and mixed races. Among negro children, however, I remarked that mesenteric disease was not uncommon.

204. *F. Race.*—After considering the distribution of heat over the globe as displayed by the isothermal lines of HUMBOLDT (see *art. CLIMATES*), and by the later researches and illustrations of Professor DOVE, I infer that less is owing to temperature than to *race* and modes of life in the causation of phthisis. There are numerous circumstances which concur with temperature in producing a climate either favourable or unfavourable to the prevalence of phthisis; and of these coldness and humidity of the air, low elevations from the surface of the ocean, and sudden and frequent vicissitudes of temperature and weather, are among the most influential elements of a climate which favours the production of this malady; while a moderately warm and dry atmosphere, considerable elevation above the sea, especially in warm countries, and regularity of season and temperature and weather, greatly diminish the prevalence of the disease, and favour recovery in the early stage of the malady. But these conditions, favourable and unfavourable, are so associated with numerous other agencies, especially with the influences of race, of social and domestic conditions, of food, habits, and modes of living, &c., that it is impossible to determine the amount of influence which may be ascribed to each.

205. There can be no doubt, however, that the disposition to phthisis existing in different *races* or *varieties* of our species should be viewed in very intimate connexion with the climates in which they reside, and with the food and modes of living adopted by them. Having ascertained the frequency of the disease in the aborigines of a country or climate, it is next of importance to know how far that frequency may be modified—diminished or increased—by change to other countries, either colder or warmer, or of higher or lower elevation, &c., and by the adoption of different food and other habits. Our knowledge of these subjects is deficient, and the difficulties in the way of improving it are many; but, before I endeavour to draw a few brief inferences closely connected with it, I shall succinctly notice such information as I have found calculated to remove a few of these difficulties. Several of the most important topics connected with this subject, and more especially in connexion with pulmonary consump-

tion, are discussed in the article CLIMATE, to which I must refer the reader.

206. In countries in which the isothermal lines of annual temperature range from 70° to 85°, phthisis appears to be rare among the aborigines; but it is more or less increased in frequency in mixed races, and in those who have migrated from very warm to cooler districts, or from a dry and elevated situation to low and humid localities; but the amount of increase under these circumstances cannot be shown. In *Upper Egypt* and other parts of *Northern Africa*, and those places in *Western Asia* where the annual range of temperature is not much above 75°, or below 65°, phthisis is very infrequent, although numerous circumstances combine to occasion external tuberculosis, especially in children, and probably also mesenteric disease; and of these circumstances the most influential are evidently insufficient and unwholesome food, and want of cleanliness. The immunity of these countries, more particularly of *Egypt*, from phthisis, was well known to the ancients from the days of ARISTOTLE; and hence this country was recommended by them as a place of residence for consumptive patients. It is stated by CHARDIN, FRYER, KAYE, KERNS, and others, that consumption is seldom observed in *Syria* and *Persia*; and MM. BROUSSAIS, BOUDET, and other French writers, remark that phthisis is rare in the natives of *Algiers* and of the *Barbary Coast*, the mean annual temperature varying from 68° to 72°. The former of these writers observe, that in *Algiers*, where periodic fevers prevail, of 40,000 cases in the French army only 62 were consumptive; and that the deaths from this disease were 1 in 102, while in the army in France they were 1 in 5. In the *West India Islands* the annual mean temperature varies from 75° to 80°. The statements respecting the prevalence of phthisis in these islands vary remarkably, and are often contradictory; but, upon the whole, it appears that this disease is not infrequent among the dark races, especially negroes who have been brought from Africa, and among creoles. Drs. MUSGRAVE, DAVY, and HUNTER say that it is rare among the indigenous inhabitants. The reports of Col. TULLOCH give five deaths from disease of the lungs annually in 1000 of the population in Jamaica; and a greater mortality from phthisis among white troops stationed in these islands than in their own country, but a much less mortality when stationed in the East Indies.

207. The *East Indies* furnish a variety of climates, according to latitude, elevation above the level of the sea, and the other elements constituting climate (see art. CLIMATE). The annual isothermal lines vary accordingly from 66° to 82°; and although cases of phthisis among the native races are not rare, especially in the jails and other places, where several causes concur with race and climate in occasioning the disease. According to the accounts furnished by STEWART, JACKSON, BALFOUR, SYKES, and others, it appears that external scrofula and phthisis occur, especially the former, in the several races in the East Indies, but in very different degrees of frequency. The writers on this subject generalize from very limited sources of observation, in respect both of climate and race. It is, however, agreed that tuberculosis, both external and internal, are most prevalent in the half-castes, or cross between the whites and natives. Col. SYKES states that in 267,456 cases of all diseases treated during five

years at the dispensaries in *Bengal and North-west Provinces* there were 115 cases of external scrofula and three deaths, and 187 of phthisis and nine deaths; thus showing a low rate of tuberculosis in the natives of India. Dr. BALFOUR states that phthisis is very rare in the natives serving as troops in the *Madras Presidency*, the deaths annually from this disease being only 4 or 3 per 1000. It should not, however, be overlooked that negroes, when removed either to the West or East Indies, are more liable to phthisis than in their native countries.

208. As to the frequency of phthisis in *Madeira* accounts are most contradictory, some writers stating extreme opinions on the subject. Upon the whole, it appears that the disease is not infrequent among the natives, and that it is even common among the lowest class. In *Malta*, in *Italy*, *Spain*, *Portugal*, *Greece*, *European Turkey*, and southern parts of *France*—in all the places to which consumptive patients are so often sent from this country—the disease is more or less prevalent; generally as frequent in all these places as in this country, and in some even more frequent. M. ANDRAL states phthisis to be very prevalent in the Mediterranean Archipelago. Mr. SPENCER WELLS says that one third of the deaths at the Royal Naval Hospital in Malta were from this malady; Drs. BURGESS, LUGOL, ANDRAL, MERVON, and others, state that phthisis is most fatal, especially in certain localities, both in *Italy* and *France*; and of these Orleans, Rheims, Montpellier, Marseilles, Nice, Rome, Naples, &c., are not the least remarkable. Mr. ANCELL gives the following table of the ratio of deaths from phthisis to all deaths in the civil and military hospitals of these countries:

Leghorn....	Civil and military.....	1 in 10·75
Florence ...	Civil .....	1 in 11·5
Rome .....	.....	1 in 3·4
Naples .....	Average of three hosp. .	1 in 2·33
	Military.....	1 in 3·85
Paris .....	Civil .....	1 in 3·25
	Military.....	1 in 12·2

In Marseilles the deaths from this disease are stated to be one in four, in Naples one in eight, in Nice one in seven; but these can be viewed as approximations only to the truth. There can be no doubt that, even omitting the deaths from other tubercular diseases, those which occur from tubercular consumption among the inmates of children's hospitals or institutions, and those brought up in these institutions, are even greater than any just noticed in either of these cities. Dr. CASPAR, of Berlin, gives the following table of deaths from phthisis in different cities in Europe and the United States, the average being about one in six:

Berlin dur. 10 yrs.	1 death fr. phthisis in 5·7 deaths
Paris.....	4 " 1..... 5·5 "
London... 2 "	1..... 6·2 "
Hamburg . 3 "	1..... 4·6 "
Stuttgart . 10 "	1..... 4·7 "
New York . 11 "	1..... 5 "
Philadelphia 7 "	1..... 7·7 "
Baltimore . 8 "	1..... 6·7 "
Boston ... 7 "	1..... 5·9 "

In *Belgium* and *Holland* phthisis is quite as prevalent as in England and France. In *Sweden* the deaths from this disease are said to be about one in nineteen of all deaths. Dr. GELLERSTEDT remarks that the mortality from this malady in

the military hospitals in Stockholm is eight in 1000, and that the life of a soldier is favourable to the production of phthisis, which he believes to be on the increase in Sweden. According to a writer in the British and Foreign Review, this disease is rare in Denmark, and still rarer in Norway, Lapland, Iceland, and the Feroe Isles. In Canada, notwithstanding the severity of the winters and sudden alterations of temperature, the air being dry, tubercular maladies, and especially phthisis, are comparatively rare. In Russia this disease is much less frequent than in the southern countries of Europe, although both Sir A. CRICHTON and Sir G. LEFEVRE state that external scrofula is very prevalent, especially in St. Petersburg and Moscow, and remark that those who bear about them scars from scrofula are supposed to be exempt from phthisis.\*

[The compiler of the "Statistical Reports on the Sickness, Mortality, and Invaliding" among the British troops stationed in every quarter of the globe arrives at the conclusion that *phthisis pulmonalis* is more prevalent in southern than in northern latitudes, and that "it is by no means likely that any beneficial influence can be exerted by climate itself."

Dr. FORRY ("Climate of the United States," p. 236) remarks, that "the conclusion that pulmonic lesions, as regards the annual ratio, are more prevalent in certain systems of climate in southern than northern latitudes, is confirmed by the statistics of the United States Army; but as we proceed in the investigation of this question, in relation to the relative influence of the seasons, the general opinions in regard to change of climate in pulmonary affections, maintained since the days of HIPPOCRATES, will be triumphantly established." Dr. FORRY's remarks, however, apply more particularly to bronchial affections than to tubercular disease. The former, we know, are in nearly all, if not all, cases, benefited by change to a milder climate, while the progress of tubercular disease is often, especially in its last stages, hastened by it. Dr. FORRY remarks, that the "old idea of the air of a marshy country being beneficial in consumption is only partially true, for among Northern troops, stationed at the South through all seasons, consumption of a tubercular nature frequently supervenes upon febrile diseases, more especially in constitutions broken down by intemperance, standing in the relation of those other sequelæ—dropsy, jaundice, and the various chronic lesions of the viscera." The same fact holds, indeed, in the United States as in Europe, viz., that phthisis is more common in the southern than in the northern parts. Thus, while in London 236 out of every 1000 deaths are caused by pulmonary phthisis, in Sweden the ratio is only 63. At St. Petersburg and Stockholm it is much less destructive than throughout Germany, and especially at Berlin, Vienna, and Paris. In the south of Europe, and especially in Italy, where pulmonary invalids resort in such great numbers for the benefit of their health, phthisis is far more common among the natives than in any part of Great Britain or New England. Cold does not *per se* prove favourable to

the development of phthisis pulmonalis, for it has been satisfactorily ascertained that the maximum of liability to the disease is found among those who suffer the least exposure to climatic variations. Dr. FORRY, however, and other writers of authority, recommend a change of climate in this disease as a remedial agent of great efficacy, and especially the peninsula of Florida, as having a temperature not less equable and salubrious in winter than that afforded by the south of Europe.]

209. "In the Southern Temperate Zone, between the isothermal lines of 40° and 70°, comprising the southern part of South America, the Cape of Good Hope, with a portion of South Africa, nearly the southern half of Australia, Van Diemen's Land, and New Zealand, all accounts lead to the conclusion that tuberculosis is much less frequent than in countries situate to the north of the northern tropic." This comparative immunity is owing to the remarkably less liability of the native races to the disease, and to the general dryness of the air, notwithstanding the sudden vicissitudes of temperature. Other conditions, either not known or imperfectly appreciated, may also concur to produce this result. In many parts of Australia, however, the quantity of dust so frequently floating in the air, during the hot and dry seasons, in some measure counteracts the other beneficial influences of the climate as respects phthisis.

210. From the statistical information which has been furnished respecting the prevalence of phthisis in different parts of the globe, and which may be consulted in the works referred to hereafter, the influences of race and of the food adopted by races and by the inhabitants of different countries, are not sufficiently considered, or are even altogether overlooked. Although statistics may nevertheless furnish much that is important on this subject, yet there are other circumstances besides these, which have not been taken into the account. Of these not the least important are, the influences of religious institutions and rites; of the states of social intercourse; of modes of living and of warming apartments in cold and temperate countries; the effects of the soil, of vegetation, of water, and of the emanations from them. Of the agency of these, either in favouring or in counteracting the prevalence or frequency of phthisis, our knowledge is very deficient.

211. From the imperfect information furnished by statistics and by other sources of knowledge, and from what I have stated under CLIMATE, I venture the following inferences as comprising most of what is known of the influence of climate, and of its more important effects in causing tubercular consumption.—*a.* Phthisis is more or less prevalent in the northern temperate zone, especially in the countries of Europe and the United States of North America.

[The deaths from tubercular consumption throughout New England vary from one seventh to one fourth of all that die, according to locality and other circumstances. The seeds of the disease would seem to be more extensively planted in the autumn and winter than at any other season. A vastly greater proportion die of the disease between the ages of twenty and thirty than at any other period; and, during this period, the number of females who die of the disease in New England is nearly double that of males. The same holds true between the ages of thirty and forty. In the

\* ["It is proved by the bills of mortality," says Sir GEORGE LEFEVRE, "that one fifth of the population dies of consumption in the British Isles, whereas the deaths in northern latitudes are infinitely fewer from that disease."—"Thermal Comfort," &c. London, 1844.—*Ann. Ed.*]

country towns of Massachusetts, the proportion of the sexes who die of phthisis is as 39.01 males to 60.99 females; in New York it is as 42.08 to 57.92; and in England, except London, it is as 46.13 to 53.87. It would seem that some causes exist in country towns to extend the disease among females, while different causes exist in cities to aggravate the disease in the other sex. It is a mistaken notion that more die of this disease on the sea-board than in the interior. From 1842 to 1848, in the four western counties of Massachusetts, Berkshire, Franklin, Hampshire, and Hampden, out of 11,803 deaths from all causes, 2398 were from consumption, or 1 in 4.92. During the same period, in the eastern counties, Essex, Plymouth, Barnstable, Bristol, Dukes, and Nantucket, out of a total of 22,930 deaths, 5333 were by consumption, or 1 in 4.29. In Boston, from 1830 to 1849, the deaths from phthisis were 1 in 6.99, or 1 in 7. In New York, from 1838 to 1843, there was, on an average, annually 1 death from tubercular phthisis to 194 inhabitants; in Philadelphia, from 1836 to 1845, 1 in 284; and in London, from 1838 to 1842, 1 in 205. In Portsmouth, New Hampshire, from 1801 to 1825, the deaths from this disease were 1 in 5.02; in Providence, Rhode Island, from 1841 to 1845, 1 in 4.58; in New York city, from 1811 to 1845, 1 in 5.03; in Philadelphia, from 1811 to 1845, 1 in 6.81; in Baltimore, from 1821 to 1845, 1 in 5.97; in Charleston, South Carolina, from 1822 to 1845, 1 in 6.58; in England, from 1838 to 1842, 1 in 6.20; in London, from 1840 to 1847, 1 in 6.97; in Paris, from 1816 to 1819, 1 in 5.55; in Geneva, from 1844 to 1845, 1 in 9.91. Statistics prove that this disease is as prevalent in our Southern States and in the West Indies as in New England, and far more fatal than in Canada and the British provinces of North America.]

212. *b.* This prevalence is most remarkable in the Caucasian race, and in the crosses of this race with any other, more especially with the negro and other dark races.

213. *c.* The natives of countries to the northward of the temperate zone are rarely affected with phthisis while they reside in these countries, and continue the habits and modes of life—of clothing, lodging, sleeping, living, and feeding—which are generally adopted by them; but when they are removed to more temperate climates, and adopt the habits and modes of life of these climates, they evince a manifest tendency to phthisis, which is probably heightened by the nostalgia to which they are subject when removed from their native countries and from accustomed pursuits, habits, &c.

214. *d.* The negro and dark races inhabiting intertropical countries, and the dark races peopling the islands within the tropics, and those in the southern temperate zone are rarely subject to tubercular consumption as long as they remain in their native countries and islands, and continue their usual habits and modes of living; but the offspring from a cross with the Caucasian race, especially when they remove to a temperate or cold and humid climate, and still more these native races when they migrate to such a climate, are even more liable to phthisis than the inhabitants of temperate countries.

215. *e.* The immunity of the natives of the countries to the north of the temperate zone from phthisis is mainly attributable to their active vocations in the open air, to the nature of their

food, and its adaptation to the temperature and climate, to the general dryness of the air, to the warmth of their clothing, whereby the skin preserves its depurating functions, and to the warmth of their sleeping-places. (*See CLIMATE, § 24, et seq.*)

216. *f.* The immunity, or comparative immunity, of the negro and dark races from phthisis, while they reside in their native countries, is chiefly to be attributed to their outdoor modes of living and exercises, to the adaptation of their food to high ranges of temperature, to the influence of miasmatic districts in counteracting the tendency to tubercular consumption, and in no small measure to the increased functions of the skin in these races, these functions being in them more decidedly supplementary of those of the lungs and liver—more actively depurative of the blood than in the white race. (*See art. CLIMATE, § 22.*)

217. *g.* The greater liability of the dark-skinned races to phthisis, when they migrate to a temperate or cold climate, is mainly attributable to the asthenic diathesis of these races, to the depressing influence of cold, especially in cold sleeping apartments, upon the vital condition of their lungs; to the blight which a low range of temperature produces upon the organs of respiration; to the change in their habits, modes of living, food, &c. The proclivity of cross-breeds to this malady is partly owing to the causes just stated, in connexion with their indolence, their debauched habits, their venereal excesses, and indoor occupations, if occupied at all. The dark races and mulattoes, when they migrate to countries whose annual range of temperature is much below that of their native climates, are disposed to congestive or asthenic inflammatory affections of the lungs; in which, owing to the low grades of vital power and vascular action, the morbid exudation is incapable of the usual changes consequent upon sthenically increased vascular action, but instead assumes the tubercular form, or that state which is incapable of organization, and equally incapable of absorption, and which undergoes the alterations characteristic of tubercular matter.

218. *h.* The Mongolian race, especially as typified by the Chinese, does not appear to be more liable to phthisis than the natives of the northern provinces of India, and of the countries in Asia between China and Europe. Of the Chinese, as well as of these latter countries, our knowledge is very imperfect as respects the relative prevalence of disease. But from what I can learn, tubercular phthisis is not a prevalent disease among them, at least as long as they remain in their native climates, and pursue their usual occupations, habits, and modes of living. How far the various races and tribes inhabiting these vast regions may be liable to this malady when they migrate to either colder or warmer countries, is not known; but the results must manifestly depend upon the many circumstances attendant and consequent upon such migration.

219. *i.* The food of man increases the disposition to phthisis in as far as it is not adapted to the constitution and wants of the races in their native countries—to the different races inhabiting cold, temperate, and tropical climates; to each of which it requires to be appropriate in its nature, as shown in the article *CLIMATE* (§ 26, *et seq.*). This adaptation of food to race and climate extends to the beverages used by the inhabitants of

different countries; the neglect of this principle of hygiene being demonstrated by the destructive effects of ardent spirits in the dark-skinned races, which are so little injurious to the natives of cold countries.

220. *k.* The influence of clothing upon the frequency of phthisis requires, equally with food, a reference to race, and the considerations which apply to the one appear in great measure to apply to the other. In all races the clothing, and in the dark races the inunctions of the skin, in addition to the slight clothing required by the vicissitudes of season and weather, tend to promote the regular discharge of the cutaneous functions; the fair-skinned races of Europe and America being those in which these functions are least active in health, and most liable to interruption.

221. *l.* Religion and religious rites may be viewed by many as exerting no influence on the frequency of phthisis or of any other disease in any climate. I believe, however, that religious rites exert some influence, but the extent of that influence I cannot state; indeed, it would be impossible to ascertain it, especially in Mohammedan countries, and in countries to the eastward and the north of the former. There can be no doubt, however, that the strictness of diet, and the rites of the Jews, notwithstanding several countervailing influences to which they have been exposed during many centuries, have rendered scrofula, phthisis, and gout less frequent among them than among other peoples in their vicinity (§ 178).

222. *m.* In our estimates of the influence of climate on the frequency of phthisis in the white races, a cold moist climate, and low situation, and without being miasmatic, or a variable and humid climate, is the most favourable to the production of this disease; while a dry, temperate, and moderately elevated situation, with a regular procession of the seasons, or a limited range of temperature, is that which is most likely to diminish the frequency or arrest the progress of the malady. Other considerations connected with climate will be entertained when the prevention of phthisis is discussed.

223. *G.* Confinement in prisons, barracks, hulks, work-houses, hospitals, and expatriation, &c., are severally productive of phthisis, both in the predisposed and in those who have evinced no marked predisposition, but in the former most especially. In prisons, hulks, and work-houses several injurious influences, physical and mental, combine to produce a more or less marked effect. Insufficient ventilation and exercise in the open air, want of light or sunshine, deficiency of external warmth, low grades of temperature, conjoined with humidity, low and moist situations, and insufficient or unwholesome food, generally combined with depression of spirits, longings after liberty, and weariness of prolonged or hopeless confinement, are the frequent causes of phthisis among the inmates of these places. Dr. BALY states that, in a period of eighteen years in the Milbank Penitentiary, nearly half the deaths and half the pardons on medical grounds were due to tubercular disease, the frequency of this disease progressively increasing after a few months' confinement; and the ratio of mortality in this prison being nearly four times more than that of the metropolis, as regards this malady. Dr. BALY has farther shown that a similar increase of phthisis among prisoners occurs in

other places of confinement, both on the continent of Europe and in the states of North America. Dr. ALLEN WEBB remarks, on the authority of Dr. GREEN, that in the jail of Midnapore, in Upper India, in  $22^{\circ} 30'$  north latitude, and  $87^{\circ} 25'$  east longitude, and in the Calcutta prison, phthisis frequently occurs, although in a hot climate, where this disease is but slightly prevalent. In these intertropical prisons the malady often follows attacks of pneumonia, or it assumes the acute and febrile form, or that described as most common in children (§ 92, *et seq.*).

224. Many of the conditions existing in prisons are, to some extent, present also in barracks and in work-houses. According to the *Army Reports*, the British foot-guards are much more liable to consumption than the general London population; and in most stations, both in temperate and in warm climates, the mortality from phthisis in barracks is much greater than among the officers or the general population of the country. As respects the guards, something may be owing to the height of the men, tall men being more frequently predisposed to this disease than those of middle size; but much more is certainly owing to the congregation of numbers in a limited space, to the irregularities and vices of a barrack life, and to the influence of a vitiated atmosphere. The results are similar, and often more remarkable, in large public or private schools, where a large number sleep in one apartment, and breathe repeatedly the same air.

225. Confinement in *work-houses* and *hospitals* is injurious chiefly by inducing tubercular disease, in some form or other, and especially in that of phthisis. In the hospitals for children this is especially the case, as shown by MM. RILLIET and BARTHEZ. The continued respiration of the air of a hospital or work-house, without removal from the wards or apartments into the open air, is even more injurious than breathing a more impure air than that in these places, when exercise in the pure open air is enjoyed during the day, the continued respiration of even a slightly impure air being more injurious than the respiration, after intervals, of a much more vitiated atmosphere. The impurity of the air in these places is caused by the numbers breathing the same air in a confined space, by the exhalation from the bodies of the inmates, and by the effluvia proceeding from diseases, morbid discharges, &c. Infants of women confined in lying-in hospitals often become generally tuberculous if they remain long in these places, as I have observed on several occasions when consulting physician to one of these institutions.\*

\* [Dr. BENNETT has truly remarked, that an observation of the circumstances which precede the disease, or its so-called causes, clearly indicates imperfect digestion and assimilation as its true origin. Thus phthisis is essentially a disorder of childhood and youth—that is, of a period of life when nutrition is directed to building up the tissues of the body. Tubercular diseases are not induced by diminishing the proper quantity of food taken by a healthy man; but if this be attempted with children, or young persons, they are a very common result. Thus, scrofula and tubercle do not originate among the *able-bodied* men in armies and fleets, to whatever privations they may be exposed; but the contrary happens in the young of founding hospitals, factories, and the poor and labouring classes of the community, as tailors, seamstresses, and others who follow sedentary employments. In the higher classes, they result from imperfect and insufficient lactation during infancy, or the irregular diet caused by carelessness or over-indulgence. No doubt they may frequently be observed in persons whose parents or relatives have been similarly affected. From

226. *Expatriation*, either by transportation for crimes or by emigration, unless the climate to which expatriation takes place be dry and temperate, is generally followed by an increase of mortality caused by tubercular consumption. Even removal from the high lands, and from the scenes of early youth, to the low and humid situations in the same latitude, although the temperature be milder, causes an increased disposition to phthisis. This is partly owing to the mental emotions consequent upon the removal so frequent in young persons thus circumstanced, and is greatly increased by the nostalgia produced in these instances (§ 213).

227. *H. Poverty, and the vicissitudes of fortune and of life*, have no mean influence in both predisposing to and exciting tubercular consumption. MM. LOMBARD, D'ESPINÉ, and LEBERT have furnished sufficient evidence that this malady is much more prevalent among the poor than among the middle and highest classes of society. M. LOMBARD states that the combined statistics of phthisis in Vienna, Paris, Hamburg, and Geneva show that the disease is doubly more prevalent among the poor than in the higher classes. Every competent observer must have remarked the occurrence of phthisis after the loss of fortune, honour, and friends, and have seen mental depression, conjoined with poverty, slowly developing this disease in its most irremediable form, in all temperaments and constitutions, and even independently of hereditary or other states of predisposition. (See also § 170, *et seq.*)

[Dr. RUSH remarks (*Med. Inquiries*, vol. i., p. 37), that "pulmonary consumption is unknown among the Indians in North America," and that "it is scarcely known by those citizens of the United States who live in the first stage of civilized life, and who have lately obtained the title of the first settlers," that "it is less common in country places than in cities, and increases in both with intemperance and sedentary modes of life;" that "females, whose habits are more sedentary than those of males, are more liable to it;" while "ship and house carpenters, smiths, and all those artificers whose business requires great exertions of strength in the open air, in all seasons of the year, are less subject to it than men who work under cover, and at occupations which do not require the constant action of their limbs."—*Loc. cit.* Hence he arrives at the conclusion that the chief method of curing consumption is the invigoration of the body by exercise and labour in the open air—a conclusion at which all known facts and experience constantly point. In regard to this disease being unknown, however, among the Indians, we have observed that it is extremely common among the Chippewas about Lake Superior, and also among the other half-civilized tribes on the borders of civilization. Its prevalence, in fact, is in proportion to the adoption of the vices, manners, and habits of the whites.]

228. V. PATHOLOGICAL CAUSES OF PHTHISIS.—Previous disorder or disease more frequently both

predispose to and directly occasion tubercular consumption than is commonly supposed; and the effect is produced not merely by calling the tubercular germs into activity where they already exist, but also by causing their formation and progressive development where no evidence either of a tuberculous diathesis or of their existence had been previously detected. If we endeavour to trace the pathological changes as they successively occur, and remark their nature, from those characterizing the previous disorder, to those which interpose between that disorder and those which constitute the incipient stage of phthisis, we shall be especially struck by the influence produced upon the vital and constitutional powers by the disorder, although apparently slight, which has occasioned this malady. Several of these disorders are so insidious, and others of a more important nature are in some cases so mild, as not to excite any apprehension as to the effects they may produce, and thus they are allowed to proceed, or are exasperated by exposure and neglect of proper treatment and regimen, until the changes or states which either indirectly lead to tubercular deposits or directly produce them more or less fully supervene. In other cases severe attacks of disease, either inflammatory or exanthematous, are injudiciously treated or neglected towards and during convalescence, owing to the desire of the patients or their friends to get rid of medical attendance; or are imprudently or prematurely exposed to the various internal and external causes of disease, and especially to those which in such circumstances more particularly depress organic nervous power, disorder digestion and assimilation, and blight the vital functions of the respiratory organs. During convalescence from epidemic and exanthematous maladies, and from inflammatory affections of the respiratory passages and organs, the patient is often left, by his own self-will and ignorance, without those means which are required to restore his exhausted vital energies, to renew the vigour of the organic nervous system, to improve digestion and assimilation, and to promote the healthy metamorphosis of the colourless chyle globules into the red globules of the blood. In many diseases, and especially in exanthematous and other fevers, the waste of the hæmato-globulin is progressive, and at the period of incipient convalescence it is generally greatest, and the blood is then poorest and most deficient in red globules. Now if these states of exhausted organic nervous influence and of impoverished circulating fluids be not improved by judicious treatment and regimen, or by change to a healthy air, &c., and more particularly if they are influenced by injurious exposures or agents, digestion, assimilation, and nutrition are liable to be perverted, and tubercular germs are thereby rapidly developed, or are directly or primarily produced.

229. *A. Previous disease of the respiratory and circulating organs* has no mean influence in predisposing to, or in directly occasioning phthisis. Frequent attacks of catarrh, catarrhal fever, influenza, hooping-cough, bronchitis, broncho-pneumonia, pneumonia, &c., are severally calculated to develop phthisis, particularly in the serofulous and lymphatic diathesis. In these diseases the evil is not always to be ascribed to the development during their course of the germs of tubercle which had previously existed, but to the primary formation of these germs or deposits during their

facts of this kind it has been supposed that hereditary predisposition, a vitiated atmosphere, changeable temperature, certain occupations, humidity, particular localities, absence of light, &c., predispose to phthisis. Very frequently several of these are found united, so that it is difficult to ascertain the influence of each. When they so operate, however, they invariably produce, in the first place, more or less disorder of the nutritive functions, and are associated with dyspepsia or other signs of mal-assimilation of food.—*Ed.*]

progress and decline, or their periods of decadence, constituting the early stage of convalescence. In this stage excited action has subsided into more or less of exhaustion, vital power is locally or generally impaired, the circulating fluid somewhat wasted as respects its most assimilated elements, and the digestive and assimilating functions considerably weakened. Diseases of the heart, especially valvular diseases, causing either congestion of the lungs or hæmorrhage from the bronchial tubes, have also no mean influence in developing phthisis; for the congestion thus occasioned is not unfrequently productive of an exudation either into the air-cells or into the parenchyma of the lungs, which passes into the tubercular form, or is converted into or becomes the nidus of fully-developed tubercles. Similar results may also follow the exudation of blood from the bronchi, especially if the fluid pass into the air-cells.

230. *B. Exanthematous diseases* are often followed by phthisis; and this latter malady is more likely to originate during the decline of these diseases, or in their early and advanced stages of convalescence, than at an early period. Of all this class of diseases there is none that is more productive of phthisis, or more rapidly develops it where the germs of the malady already exist, or where a predisposition to it is present, than *measles*, and this is more especially remarkable in persons about or above the age of puberty. I have often observed persons who, by diathesis, hereditary predisposition, or other circumstances, were possessed of a consumptive tendency, pass through measles without any marked pulmonary complication, or any pulmonary disorder that could be detected by auscultation or otherwise, and yet, during the progress of advanced convalescence, or soon afterward, indications of incipient phthisis have appeared, especially if any exposure or want of care had favoured the development of the malady. In this, and in others of the exanthemata, the decadence of the disease, and the consequent convalescence present, as just stated, the most favourable occasions for the origination of phthisis, and these should be carefully guarded against.

231. Of all the exanthemata, there is none so unfrequently followed by phthisis as *small-pox*. It would appear that this latter malady either carried off most of those predisposed to phthisis, when small-pox was a more prevalent disease than it is now, or it destroyed the predisposition to phthisis. I have long remarked, and I believe that others have also remarked, the very rare occurrence of phthisis in any one even but slightly marked with small-pox. It is manifestly otherwise with *vaccinia*, for what I have stated with respect to its influence on the frequency of *SCROFULA* (§ 47-49) is equally applicable to phthisis. It does not appear that *scarlet fever* is influential in producing or developing phthisis farther than that the debility consequent upon it, during convalescence, requires a careful protection from exposures and other exciting causes of this latter malady. Scarlet fever is often attended or followed by enlargement and suppuration of the glands of the neck, especially in serofulous subjects; and in these cases, as well as in other serofulous cases, when these glands suppurate, the liability to tubercular consumption is thereby greatly diminished.

232. *C. Suppressed or excessive secretion or excretion* is often more or less concerned in occasioning phthisis. The suppression of an accu-

tomed evacuation or discharge, or the drying up of an issue, seton, or ulcer, or the healing of a fistulous ulcer, as *fistula in ano*, has been followed by phthisis; but in all such cases as have fallen within my observation the disease had commenced previously, or had even made some progress, the suppression of the discharge, especially of hæmorrhoids, or the catamenia, or of the cutaneous excretions, having been followed by a more acute form of the disease, or having developed a chronic, or slow and insidious state of phthisis, into the congestive, inflammatory, acute, or hæmorrhagic, according to the diathesis or habit of body of the patient.

233. On the other hand, excessive discharges, whether hæmorrhagic, secretory, or excretory, may so weaken the constitutional powers—may so depress organic nervous energy, and impoverish the blood, by wasting its hæmato-globulin, as to be followed by tubercular phthisis, either where a predisposition to it already existed, or where causes tending to blight the vital condition of the lungs were in operation—as cold, humidity, &c.; excessive losses of blood, by operation or from hæmorrhoids, from menorrhagia, flooding, &c.; prolonged or improper suckling, diarrhœa or dysentery, enteric fevers, masturbation, and venereal excesses, have severally not unfrequently either caused or developed phthisis, especially where a predisposition to it was present.

234. *D. Impaired organic nervous or vital power*, or debility, whether hereditary, original, or acquired during childhood, youth, or maturer age, is more intimately connected with the occurrence of phthisis than is generally supposed, and is directly concerned with the causation of the impaired conditions of digestion, assimilation, and nutrition, which constitute a large portion of that circle of morbid actions characterizing the commencement and early stage of tubercular consumption. (*See DEBILITY.*)

235. *E. Morbid states of the circulating fluids*, both the chyle and blood, that are so often present at an early stage of phthisis, or even before this state has manifested itself, are the first results of impairment of the organic nervous power; and although comparatively rarely declared in the form of anæmia or chlorosis, yet they consist of a greater or less deficiency of the hæmato-globulin, and especially of the red globules, with an excess of the colourless globules, and a weakened crasis or diminished vital cohesion of the fibrin, and consequently of the coagulum.\*

\* [It is now admitted by the best pathologists that tubercle is an exudation of protein material in a solid form and of a low grade of development, its shape depending chiefly on the tissue in or upon which it is deposited. It is the opinion of ROKITSANSKY that an especial immunity against tubercle is afforded by an abnormally venous condition of the blood, from whatever cause this may originate; and also by congenital malformations of the heart or great blood-vessels; morbid alterations of the same; deformities of the chest, producing contraction of its cavity; annihilation of the function of one lung by pleuritic effusion; abdominal growths, preventing the free descent of the diaphragm; chronic pulmonary catarrh; emphysema and bronchial dilatation; in short, by whatever prevents due oxygenation of the blood. Pregnancy, also, delays the advance of tuberculous disease, by impeding the respiratory function, thus inducing a venous condition of the blood; and aneurismal and tuberculous diseases do not coexist, because the deposits on the inner surface of the sac exhaust the fibrinous constituent of the blood. Typhus and the exanthemata do not often, if ever, attack the tuberculous, although they may lay the foundation of phthisis. Persons labouring under intermittents, goitre, or rachitis, are seldom liable to tubercular disease; and the same

236. VIII. OF THE OPERATION OF THE CAUSES OF PHTHISIS.—*Phthisis*, whether hereditary, congenital and proceeding from causes affecting the parent, or produced by causes acting during early or mature age, generally arises from a concurrence of causes, one or more of which may be much more effective than the rest; they may act either contemporaneously or successively, or the influence produced by one or two may be reinforced or determined by others acting subsequently.

237. i. The causes, then, either affecting the parents, and the offspring through them, or the individual only during early childhood, or subsequently, in the many modes of combination or succession that most necessarily arise from their numbers, are of such natures as to impair vital power, especially as manifested by the organic nervous system, and by the organs and functions endowed by this system.

238. ii. As this system actuates the vascular system and the blood, and as it influences also the digestive, assimilating, and nutritive functions, the secretions and the excretions, so it necessarily follows that causes which depress or exhaust, or otherwise impair the influence or power of this system—the organic nervous—will co-ordinately affect the states of the assimilating functions, of the blood, and of nutrition.\*

239. iii. The following may thus be inferred as the successive or morbid phenomena resulting from the action of the causes of phthisis, whether occurring singly, or in various combination, or in succession: 1st. Depression of the organic nervous or vital power of the frame, or an imperfect development of this power, owing to hereditary or congenital, or to more immediate or direct causes operating in early or advancing epochs of life; 2d. Morbid states of the circulating fluids, especially of the chyle and blood, commencing with the slow or imperfect development of the chyle globules, and followed by a slow or impaired metamorphosis of these and the blood globules, or of the former into the latter—the plasma or *liquor sanguinis*, with its fibrin, being deficient in vital endowment; 3d. A wasting or diminution of the red globules, and an impairment of the crasis or vital endowment of the plasma by excessive secretion and excretion from the lungs, skin, and bowels; 4th. The nutrition and vital cohesion of the tissues—the organization of the frame ultimately suffers.

240. iv. These changes in the organic nervous influence or vital power, in the circulating fluids, and in the nutrition of the structures, produced by the causes of phthisis, may take place contemporaneously and co-ordinately; but they may more reasonably be supposed to advance in succession, will hold true in regard to cancer. No doubt is now entertained in regard to the identity of tuberculous and serofulous matter, they both having the same elementary composition, undergo the same changes, are produced in the same way, and produce the same effects on the tissues in which they are deposited.—*Ed.*

\* [Prof. AUSTIN FLINT observes on this point as follows: "Tuberculosis has been supposed by some distinguished authors to be often preceded and accompanied at its commencement by notable disorder of the digestive function. *Such has not been the fact in my experience.* I have not observed that dyspeptics are prone to become affected with tuberculous disease; and, conversely, tuberculosis has seemed to me, oftener than otherwise, to originate without being attended by any marked evidence of gastric disorder. So far, then, from dyspepsia contributing any ground for anticipating that the evidence of tubercles will be discovered, I have come to regard it in an opposite light."—*Loc. cit.*—*Ed.*]

cession, however rapidly, impaired organic nervous power accelerating and increasing the other subsequent changes. That this procession of morbid changes actually obtains may be inferred from the modes in which the causes may be presumed to operate; for those causes which primarily and chiefly affect, by depressing or impairing, or imperfectly developing, organic nervous power, as hereditary influence, the depressing emotions of mind, &c., may rationally be presumed to operate consecutively, and to no slight extent also impede and disorder digestion, assimilation, and the healthy metamorphosis of the chyle and blood globules, and ultimately the nutrition and vital cohesion of the tissues. Many other causes which more directly tend to prevent the development of the chyle and blood globules, or to promote their waste or destruction, as insufficient food, increased discharges, &c., depress organic nervous or vital power, while they impair or arrest nutrition. Certain causes, again, exert a still more extended influence; for they act directly and manifestly, both by depressing or exhausting vital power and resistance, and by accelerating or increasing the waste and destruction of the hæmato-globulin; nutrition, and the healthy conditions of both the fluids and the tissues being more or less impaired. The most influential of these last causes are premature or excessive sexual indulgences in either sex, masturbation, excessive secretions and discharges, sedentary occupations in ill-ventilated and over-crowded apartments, impure air of any kind, confined and insufficient exercise, defect of light and sunshine, &c.\*

241. IX. TREATMENT OF TUBERCULAR CONSUMPTION.—i. HISTORICAL SKETCH OF THE TREATMENT RECOMMENDED BY AUTHORS.—It was remarked by Dr. YOUNG, one of the greatest of the many names that adorn the literature and science, not only of our profession, but of our country, in his learned work on "*Consumptive Diseases*," that although we may not obtain from the medical writings of the ancients any great variety of information immediately applicable to practical purposes, we may still feel a sufficient interest in the history of a science which deeply engages our attention, to induce us to enquire how long the

\* [Dr. HUGHES BENNETT maintains, with great probability, that the peculiarity of phthisis is, that an excess of *acidity* exists in the alimentary canal, whereby the albuminous constituents of the food are rendered easily soluble, while the alkaline secretions of the saliva and of the pancreatic juice are more than neutralized, and rendered incapable either of transforming the carbonaceous constituents of vegetable food into oil, or of so preparing fatty matters introduced into the system as will render them easily assimilable. Hence an increased amount of albumen enters the blood, as shown by chemical analysis, while fat is largely supplied by the absorption of the adipose tissues of the body, causing the emaciation which characterizes the disease. In the mean while, the lungs become especially liable to local congestions, leading to exudation of an albuminous kind, which is tubercle. This, in its turn, being deficient in the necessary proportion of fatty matter, elementary molecules are not formed so as to constitute nuclei capable of farther development into cells; they remain, therefore, abortive, and constitute tubercle corpuscles. Thus a local disease is added to the constitutional disorder, and that compound affection is induced which we call phthisis pulmonalis—consisting of symptoms attributable partly to the alimentary canal, and partly to the pulmonary organs. We may, therefore, conclude with Dr. B., that, 1. An oily emulsion must be formed to constitute a proper chyle to be converted into blood; 2. That in pulmonary and other forms of tuberculosis, this process is interfered with; 3. That, consequently, a state of the constitution is induced favourable to the deposition of tubercular exudation into various tissues, but especially into the pulmonary organs.—*Ed.*]

few truths which are fully established with regard to it have been sufficiently demonstrated. "When, indeed, a fact is once well authenticated, no accumulation of authorities can be sufficient to invalidate its credibility; yet we cannot help placing a greater degree of confidence in opinions which we are, for other reasons, inclined to adopt, when we are informed that they are sanctioned by the observations of the most respectable authors of every age." It is necessary to premise that, until the commencement of the nineteenth century, the sub-acute and chronic forms of *bronchitis* were very generally described and treated as forms of *consumption*, and even as true *tubercular phthisis*; and that this want of precision in the diagnosis of these diseases led not only to a much greater diversity of opinion as to their treatment, but also to a marked difference in the reputed results of the means employed. The general misconception existing among writers respecting the precise nature and seats of bronchitis, and tubercular formations in the lungs, and their consequences, should be kept in recollection in reading the following sketch; for it will then become apparent that much of the benefit produced by many of the means recommended was actually not manifested in the cases of tubercular consumption, but in those of sub-acute, or asthenic, or chronic bronchitis. (See *art. BRONCHITIS*.)

242. HIPPOCRATES frequently mentions tubercular consumption by the name *phthisis*, *phthoe*, and *empyema*, and states that the age most liable to it is from 18 to 35. He notices many of its most prominent phenomena; as the taste and appearances of the expectoration, the pain between the back and sternum, the frequency of hæmoptysis, the quick, wheezing respiration, the cough, the condition of the hair and nails; the sweats, diarrhoea, emaciation, pleural adhesions, &c. His treatment is not always consistent with itself. He advises caustics externally, emetics, purgatives in moderation, oxymel, milk diet, especially asses', goats', and mares' milk, warm from the animal; walking exercise; avoiding the extremes of heat and cold. In addition to these, several other, and often opposite means, are advised in different parts of his writings, to which it is unnecessary to refer.

243. In the works of ARISTOTLE is to be found the earliest notice of the opinion that phthisis is infectious. He states that this disease makes the breath corrupt and offensive, and that those who approach the diseased person breathe air vitiated by him. PLAUTUS mentions resin and honey as being employed by the Romans for hæmoptysis; and DIOSCORIDES, the physician of Cleopatra, and the greatest writer on the materia medica in ancient times, recommends sulphur—a substance which has been employed in various forms, even down to the present time. ARETÆUS considers ulceration of the lungs as genuine consumption, called it *phthoe*, and gives a good description of the disease. Most of the chapter on the treatment is lost, but in what remains milk diet and sea-voyaging are strongly advised.

244. CELSUS states that, in genuine consumption, a long sea-voyage and change of climate are most advisable, if the strength will permit, and the climate of Alexandria is preferred by him. He remarks that the worst air for any disease is that in which it has originated. Among various other means he recommends milk diet, with garlic, leeks, &c., with vinegar; farinaceous articles,

occasionally some mild animal food; flour boiled with mutton suet, and some light and austere wines. He advises the cautery on various parts of the chest, and the ulcers not to be healed as long as the cough continues. He mentions several other remedies, as horehound with honey; the juice of plantain; garlic in wine, raw or soft; eggs with sulphur; hyssop; turpentine boiled with butter and honey; carriage exercise; sailing on a long sea-voyage. For hæmoptysis he advises bleeding, cupping, wool wet with vinegar to be placed where pain is felt; a cool apartment, and rest. The elder PLINY enumerates many substances as specifics for consumption, especially ammoniacum, a course of milk in the mountains, the juice of plantain, a linctus of betony with honey; goats' fat in gruel, or with honey and water, and a little rue, and various other means less rational.

245. The works of GALEN furnish many prolix and digressive discussions on phthisis. The expectation of cretaceous concretions was first noticed by him. He believes in the infectious nature of the disease. He prescribes vinegar much diluted with water for the hectic; bleeding, an emetic, purgatives, frictions, baths, exercise, a mild opiate at night, and removal to *Stabie* for the advantages of the air and milk of that place. He remarks that the air of that place is dry, the pastures healthy, the hills of moderate height, three miles from the Bay of Naples, sloping gently to the west, and near to Vesuvius, which makes the air still drier by its volcanic heat, and defends it from the northwesterly winds. At *Stabie*, he says that the milk of cows is used; but he considers asses' and goats' milk preferable, the former being lightest, the latter of an intermediate nature. In order to allay the cough and improve the expectoration, he prescribes frankincense, myrrh, saffron, squills, liquorice, nastich, tragacanth, &c., with sirup of grapes and honey. When the discharge is excessive, he employs opium and castor, or aloes, mastich, and saffron; or the juice of hyoseyamus with pepper; or a lozenge of *Scribonius Largus*, containing liquorice, myrrh, turpentine, and tragacanth; or sulphur, with cardamoms and cinnamon. Most of GALEN's prescriptions were copied from those of the physicians who had preceded him. Various modes of preparing the *diacodium*, consisting chiefly of sirup of poppies and honey, are given; and for dry coughs, iris with honey is recommended; and for hæmoptysis, roses, gum, tragacanth, bole, linseed, and polygonum; and for the consumption consequent on it, iris with hyssop, bitter almonds, the juice of squills, with honey, southern-wood, and various other substances.

246. CÆLIUS AURELIANUS gives a tolerably correct account of the disease by the name of *phthisis* or *phthoe*. The medicines he prescribes are honeyed water, fenugreek, iris, aristolochia, arum, and horehound; also fir-cones, with honey and liquorice; and *diacodium*, with butter and honey. Sailing, especially to a distant climate, and reading aloud, are also advised. He censures the use of emetics, and considers the cold bath dangerous. For hæmoptysis he directs astringent electuaries, and pomegranate with aloe, as advised by THEMISON. If the hæmorrhage continue in moderation, he prescribes blood-letting on the third day, as inflammation will then take place; but if the symptoms are urgent with dispnoea, bleeding should be practised at an earlier period. ORIBA-

sius gives merely an abstract of GALEN's practice, and remarks that a milk diet is of more importance than all other remedies. AETIUS makes a similar remark respecting asses' milk. He also recommends venison fat dissolved in soup, and caustics to the chest. ALEXANDER TRALLIAN gives ripe fruit for the hectic of phthisis, especially grapes. When concretions are expectorated he employs a cooling diet; and for the cough the juice of lettuce with liquorice; and the diacodium for relieving thirst and excessive perspiration. He also mentions the hermodactyls and their combinations. In the writings of PAULUS ÆGINETA and ACTUARIUS, there is nothing beyond what is contained in the works of GALEN.

247. The *Arabian* writers exhibit no views of the nature and treatment of phthisis different from those which have been given by the Greeks. RHAZES, the most original of these, strongly recommends a milk diet, and fumigations from a mixture of orpiment, aristolochia, myrrh, styrax, and galbanum in equal parts, with a sufficient quantity of butter. AVICENNA prescribes camphor lozenges; in the early stages, bleeding; and generally a dry air, a milk diet, and sugar of roses. In all else he closely follows GALEN.

248. The medical writers of the fifteenth, and of the first half of the sixteenth century, follow the doctrines and practice of the ancients, with the exception of PARACELSUS. He recommends a powder for phthisis, containing crude antimony and crocus martis. He considers diet to be of the greatest consequence, and advises a bath to be tried containing a decoction of herbs with sulphur. FUCHSIUS was the first to notice digitalis, but in a very imperfect way. FERNELIUS, whose reputation was high in the sixteenth century, praises asses' milk, and small bleedings for hæmoptysis; in all things he principally followed HIPPOCRATES. LOMNIUS notices the infectious influence of the expectoration and breath in phthisis, and the hereditary character of the malady. The work of NICOLAS PISO is only a compilation from GALEN and other ancient writers. PROSPER ALPINUS merely states, in his work on the Diseases of Egypt, that phthisis is one of the endemic maladies of the country. FORESTUS was among the first to give cases in detail; but he professes merely to follow the doctrines and practice of GALEN. Among the means which appear to have been most beneficially used by him in consumptions are asses' and goats' milk, and sulphur with the white of egg. SCHENCK notices the use of turtle broth, and snails fattened on sugar and flour for hectic; but his materials are chiefly compiled from other writers. Most of the remedies he mentions have been already noticed; but we find that AVENZOAR prescribed olive oil, RUBÆUS sulphuric acid, and J. G. SCHENCK the balsam of sulphur, in phthisis. The voluminous writings of BALLONIUS or BAILLOU, a physician in large practice in Paris at the end of the fifteenth century, contain nothing more deserving notice respecting phthisis than a remark as to the frequent occurrence of the disease in those who have nursed others affected with it.

249. POTERIUS, a physician to the French court, struck out novel modes of practice in this disease, but kept the preparation of most of his chemical medicines secret. These, as far as they are known, seem to have been oxydations of tin, of mercury, of silver, of antimony, of gold, &c., with various other substances. He employed su-

gar of lead as a refrigerant; and a preparation which, under the name of the anti-hectic of POTERIUS, long enjoyed a great reputation. Dr. YOUNG states that this medicine appears to have consisted of two parts of tin and one of antimony, oxydated by means of nitre. He professes to have cured phthisis by giving five drachms of balsam of sulphur every morning with sirup, and the anti-hectic in the evening, sulphur lozenges and iris being held constantly in the mouth, with a diet of wine and animal food. The balsam of sulphur he recommends to be made with the oil of almonds, and given in milk; other oils make it too heating. SPIGELIUS states that consumptions are more common in England than elsewhere, owing to the habit of confining the chests of females by tight dress; and that in Venice, where this habit does not exist, females are more healthy.

250. SENNERTUS, whose works were very generally confided in at the commencement of the seventeenth century, closely follows GALEN. He considers the debility, diarrhoea, &c., to depend, in phthisis, upon an acrid or morbid secretion generated in the lungs. He prescribes many medicines, especially rhubarb, with infusion of roses and goats' whey; and he cautions against too copious evacuations of any kind. He advises an issue in one or both arms, if the debility and emaciation be not extreme. He remarks that sulphur was first recommended in phthisis by DIOSCORIDES; and he makes favourable mention of honey, roses, horehound, hyssop, &c. He quotes other authors in favour of guaiacum and ginseng. BONTIUS, in his *Medicine of the Indies*, gives a case in which he supposes that fragments of the bronchi were expectorated, but which are mere false membrane formed on the bronchial surface. For true consumption he praises his opiate extract of saffron, which, he says, stops bleeding, quiets the cough, and has alone cured many desperate cases. He also prescribes conserve of roses with poppy seeds and sulphur, and decoction of ginseng or of sarsaparilla. Verily there are much worse modes of treatment employed in recent times than those adopted by SENNERTUS and BONTIUS. TULPIUS furnishes nothing more deserving notice than the advantage obtained in a case of the disease by eating oysters daily. FABRICIUS HILDANUS describes several dissections of phthisical subjects, and notices the complication of pulmonary with mesenteric lesions, and the presence of calcareous concretions in the lungs. He relates several instances of successful recourse to setons.

251. Our countryman BENNET, as VAN SWIETEN and Dr. YOUNG very justly remark, has much surpassed his predecessors, and most of his successors also, as a writer on consumption, which he experienced in his own person. He pays marked attention to the breathing and the sputa, to the prognosis, and to the several contingent affections in the course of the disease. For hæmoptysis, leading to phthisis, he advises bleeding, warmth to the extremities, and bleeding from the feet in females, if the catamenia be scanty or suppressed. He recommends milk and milk diet, but prefers medicated whey, and reprobates the use of saccharine substances, as productive of an injurious fermentation. He considers the best expectorants to be those which contain resin and turpentine. BENNET also has recourse to frictions and fomentations, and to balsamic fumiga-

tions. These last should consist, in his opinion, of frankincense, turpentine, and styrax, with cinnamon, colt's-foot, and other articles, made into a powder or troche, and burned on coals. He prescribes also mixtures of herbs, on which boiling water is poured, and the vapour to be inhaled by holding the head over the vessel containing them. Issues are much praised, and, according to my experience, with very great justice. He directs them in various situations, according to the symptoms, and he considers that they may be kept sweet by using peas of orris root, and when the discharge should be promoted equal parts of hermodactyls and wax. He recommends Welsh flannel to be worn next to the skin, and not to be too frequently changed. Animal food, neither very fat nor lean, is allowed, and a gentle emetic is given when the stomach is loaded, and a decoction of sarsaparilla and other woods with ginseng is recommended for drink. If we except the recent employment of cod-liver oil in phthisis, in what, it may be asked, has the treatment of this disease been advanced since the appearance of the work of BENNET, by the voluminous writings of specialists and stethoscopists in recent times?

252. The continental writers of the middle of the seventeenth century afford very little information as to the treatment of phthisis beyond what was previously known. SILVATICUS confided chiefly in bleeding, issues, and sulphurated lozenges. RIVERIUS notices the infection of persons who had nursed phthisical patients. Among the many substances already mentioned he particularizes guaiacum, Peruvian balsam, and the stomachic, and the diaphoretic gold, of POTERIUS. BARTHOLIN furnishes nothing deserving notice farther than that sitting apartments may be made, by suitable vapours or medicated effluvia, useful substitutes for a voyage to Egypt or other warm countries. SYLVIVS attributed phthisis to the existence of glandular tubercles, which, when in a state of suppuration, constitute the vomica. For the cure of the disease he administers opiates, demulcents, and emulsions, fumigations, decoctions of the woods, hermodactyls, &c. He praises balsam of sulphur, prepared slowly with oil of anise seed, and says that it facilitates expectoration and relieves the breathing. He considers the milk of sulphur to be much inferior to it. To promote the appetite he prescribes the elixir proprietatis, which is made of myrrh, saffron, aloes, sulphurous acid, and spirit of wine, digested together. The diet he allows comprises wheat bread, broths, milk, yolks of eggs, biscuits, with a little generous wine.

253. GIDEON HARVEY gives a tolerably good description of phthisis, notices bleeding, and remarks that great caution is required in practising it. He prefers whey to milk, gives it liberally with conserve of roses, and mentions the imperatoria as being recommended to him for this disease. WILLIS remarks that the atmosphere of towns is not always unfavourable to consumptive patients, for he has observed many have better health and less cough in London than in the country. He prescribes sulphur in all forms, several balsams, and tar-water. After bleeding, he advises narcotics, the muscus pyxidatus, warm bathing, frictions, blisters, &c. DIEMERBROECK mentions the case of a person who was cured by taking goats' milk thrice daily for three months, without any other medicine. BONETUS furnishes some information as to the lesions formed in

phthisical cases, but it is of a very loose and imperfect kind, chiefly furnished by former writers, many of them of little reputation.

254. Of the writings of SYDENHAM, which have been extravagantly praised, but which are now more justly estimated, Dr. YOUNG justly observes that, "among the practical writers on consumption he cannot be considered, even by his warmest admirers, as holding a distinguished rank." His pathology of the disease hardly deserves notice. For a confirmed consumption, medicines are, he remarks, of little use; but bleeding, mild purgatives, and pectoral remedies may be tried, with inaccessants or attenuants, according to circumstances. For the fever he gives refrigerents, asses' milk, emulsions, and opiates. For hæmoptysis he directs bleeding, cathartics, and the avoidance of animal food. Horse-exercise is very strongly recommended by him; and he states, with the truth that many cannot fail to appreciate, that riding cures consumption as certainly as bark cures intermittents. Carriage-exercise is also praised by him. For simple cough he prescribes abstinence from wine and meat for a few days; ten drops of anised balsam of sulphur, taken occasionally on a lump of sugar; lozenges containing liquorice, alecampane, anise seed, angelica, iris, and sulphur; and a linctus of oil of almonds, with sirup of capillaire and violets. If the cough be obstinate or attended by fever, he orders bleeding and cathartics; and if the patient becomes consumptive, ten drops of Peruvian balsam three times a day, a decoction of bitter plants, riding being the chief remedy. G. HARVEY, after ridiculing the treatment of consumption proposed by his predecessors, concludes that there is a single cheap remedy which does wonders; but this remedy he conceals. The only remark made by him deserving notice is, that hectic is generated by the pus which enters the blood; for the disease is partly an affection of the fluids, and not, as has sometimes been supposed, of the solids alone.

255. The *Phthisiologia* of MORRIS was for more than a century the basis of practice in consumption, although in all most important matters it was anticipated by the writings of BENNET. There remain, therefore, but few topics deserving notice. Chalybeate waters are considered by him as preferable to all other means for the prevention of the disease, especially in scrofulous constitutions; he directs them to be taken freely, either cold or warm. He considers catarrh to be the most frequent cause of phthisis; and infection sometimes to occur, for he believes that it may be communicated to a bed-fellow. When proceeding from this latter cause, he considers it to be most fatal. He recommends bleeding in the early stage, but views it as fatal in the advanced stages, and opiates for the cough with purgatives, as the aloetic tincture. After bleeding, emetics are viewed by him as of great benefit, in the first stage, but they ought to be followed by opiates. He frequently prescribes his stomachic pills, consisting of aloes, myrrh, mastich, saffron, cloves, wormwood, nutmeg, calamus, mace, rhubarb, musk, cardamoms, &c. In scrofulous and scorbutic consumption he recommends pills of gum ammoniac, with benzoïn, balsam of Peru, and sulphur. But in all forms of phthisis, especially in the more advanced stages, he considers cinchona the great and general febrifuge. Several forms and complications of consumption

are particularized by him as requiring different or additional means of cure. He says that, in asthmatic phthisis, opium is injurious, by increasing the dyspnoea; but that ammonia and the citrate of potass are most useful remedies. In the melancholic and hysterical phthisis, emetics, he avers, act like magic, and opium is particularly requisite. For phthisis complicated with hæmoptysis, after venesection and other remedies, he gives the bark in doses of a drachm every four hours. He remarks that calculi may form in the lung, may lie there a long time inactive, or they act as foreign bodies. Consumption consequent on syphilis he considers to be of an asthmatic nature. Chlorosis often passes into phthisis, he justly observes, by imperceptible degrees, if not treated by chalybeates and purgatives. When he suspects internal ulceration, he gives from 20 to 30 grains of calomel every third or fourth morning, and the diaphoretic antimony at night. BRUNNER states that he "entertained strong doubts of the propriety of MORTON'S practice of giving cinchona in hæmoptysis, till he found by experience that it succeeded, where every thing else had failed."—YOUNG, p. 203.

256. ERMÜLLER recommends emetics early in phthisis, and a diet of milk and raw new eggs. BAGLIVI furnishes us with nothing novel, excepting that he supposes ipecacuanha to be the best remedy for this disease, and for all hæmorrhages and discharges. WEPFER furnishes some of the earliest information as to tubercles. In his observations on diseases of the head, he gives an account of an *endemic* consumption at Waldschut, on the Rhine, where there is a cavern in which mill-stones are dug and wrought. The air is there always hot—even in winter, and a very fine dust floats in it. All the workmen employed in it become consumptive, if they remain a year, or even a shorter time.

257. STAHL'S opinions as to the treatment of phthisis are not worthy of his reputation. His remarks are chiefly directed to the non-efficacy of most of the means which had been advised up to his time, and many of his observations are just. He reprobates the use of balsams, opiates, expectorants, cinchona, myrrh, balsam of sulphur, &c., and confides chiefly in bleeding, and nitre in moderate doses; and asses' milk, he says, is fit only for asses. The too general or inappropriate use of these and other medicines—the universal employment of a medicine because it has been advised, or found useful in one or even a few cases, is mere empiricism. It is the appropriate exhibition of a medicine to inferred pathological conditions which constitutes rational practice. He remarks that females are more frequently consumptive than males; but they have a greater chance of escaping its fatal termination. He considers exercise on horseback or in a carriage to be the most beneficial remedy for phthisis. FULLER agrees with STAHL as to riding on horseback being most salutary in this disease, when "without fever or ulcer;" but he adds that "the patient must be a Tartar, and live on his horse."

258. F. HOFFMANN, the rival of STAHL in reputation, fully discusses the treatment of hectic fever and phthisis. He remarks that hectic attended by indigestion may often be relieved by an emetic of ipecacuanha, followed by a dose of aloes. If amenorrhœa be a concomitant, bleeding in the feet and deobstruents are prescribed by him. If mesenteric disease complicate phthisis,

as often observed in children, warm bathing, nitre, sulphate of potass, and sal-ammoniac are recommended. In all hectic he considers milk a principal remedy, especially woman's milk, asses' milk, goats' milk, or cows' milk, with manna or conserve of roses, or with Seltzer-water. He also ventures to give the tincture or infusion of roses, cascarilla, cinchona, and nitre. He gives the muriate of potass when the appetite is weak. Bleeding, he says, should be practised with much caution. He adverts to a patient who was kept alive thirty years by losing some blood twice a year, and drinking a decoction of ginseng and sassafras. The treatment which he more especially advises for phthisis is somewhat similar to the foregoing. He thinks justly that, where a predisposition to the disease exists, it may be called into action by attendance on a consumptive patient. When a milk diet occasions acidity, he substitutes whey; with which, or with milk, mineral waters, or lime-water, may also be mixed. He considers the best laxatives in phthisis to be manna, magnesia, rhubarb, or senna taken in milk; and milk or whey with parsley-seeds, or celery-seeds, to be the best diuretics. He is not favourable to the use of gum-resins or balsams, if they occasion, or if given during, febrile action. Myrrh, saffron, copaiba, opium, honey, wax, spermaceti, and oil are viewed more favourably. In the young and plethoric, small and frequent bleedings, air, exercise, and warm baths are, he believes, the best prophylactics. He considers half the cases of consumption to originate in hæmoptysis, and he advises that the bleeding should not be stopped too soon by astringents. In advanced cases, bleeding to the amount of an ounce only, often relieves the breathing. He says that emetics and strong cathartics are injurious. He makes favourable mention of issues, and of a stomachic elixir, composed of myrrh, saffron, nutmegs, and buck-bean, which is to be taken at meals, consisting chiefly of milk diet, broth, and ptisan. For the colliquative perspiration he gives nitre and opium in small doses. He often prescribes also sulphur and diaphoretic antimony; and the combination of milk with mineral waters is much praised by him. It will be seen that the treatment adopted by this great physician is, in most respects, of great excellence, and when employed appropriately to the circumstances, form, and stage of the malady, by no means inferior to any adopted at the present day.

259. MUSGRAVE was the first to point out the connexion of phthisis in some instances with irregular gout. The treatment he advises is not materially different from that recommended by BENNET, HOFFMANN, and others. BOERHAAVE furnishes no information as to the treatment of phthisis in any way worthy of his great reputation; his practical judgment appears to have been overlaid by his hypothetical doctrines. The respectable synopsis of ALLEN furnishes one very good suggestion, namely, the propriety of the liberal use of buttermilk in consumption. He also believes in the contagious nature of the disease in certain circumstances favourable to its operation. WHERLHOF comes to the defence of cinchona and MORTON against the attacks of STAHL. DOVER, in his ancient Physician's Legacy, appears in his heroic character of buccaneer in the treatment of phthisis. He advises a frequent repetition of bleeding in small quantities, horse-exercise, crude quicksilver in large quantities, a

substance much in fashion at the commencement of the eighteenth century; and anise seed and crocus martis made into pills with the balsam of Locatelli, in the morning, and elixir of vitriol in the afternoon. He gives also his powder, which originally contained nitre instead of the sulphate of potash of the modern powder. He advises the antiphlogistic regimen.

260. P. DESAULT deserves notice for his having been the first to contend that tubercles in the lungs constitute the essence of consumption; that they are generally antecedent to hæmoptysis; and that ulceration of the lungs is merely an effect, and not a cause. He adds nothing to what has already been stated as to the treatment. JUNKER, the methodizer of the doctrines of STAHL, furnishes but little information respecting phthisis, and almost none deserving notice, excepting his approval of riding, and his disapproval of warm balsams and aloes. WAINE-WRIGHT considers CHEYNE correct in concluding that the quantity of blood is much diminished in hectic, and thinks that pectorals and balsamics are injurious, unless they serve as stomachics and diuretics. He prescribes gentle emetics, mild stomachics, riding, pure air, frequent blisters, and a light, digestible diet. Dr. THOMSON is in favour of small doses of antimonial wine in consumptions.

261. Dr. HUXHAM's reputation induces a desire to know his practice in phthisis. He remarks, that catarrh occasions this disease only when tubercles had previously been formed in the lungs, and that the malady may be fatal before an ulcer is formed. Instead of sweet, oily, emollient, and other substances, which often disagree with the stomach, and occasion acidity and diarrhœa, he employs gentle diaphoretics, blisters between the shoulders, mild cathartics with anodynes interposed, the decoction of cinchona, with guaiacum and styrax, and inhalations of drying fumigations. He advises those of a consumptive tendency to remove into the country in the spring, and to lose a little blood as a precaution. RUSSEL's work on glandular decline is of some importance as recommending a remedy within the reach of most persons, and one of great efficacy when judiciously employed, namely, sea-water, especially when taken internally, warm or cold, according to the circumstances of the case. He employs it also externally, at different temperatures.

262. Dr. MEAD insists on the intimate connexion of phthisis with scrofula, and considers that the use of bark in the disease is indicated by the periodicity of the attendant fever; but he believes it to be injurious when the lungs have become ulcerated. Goats' milk and whey are recommended; and when milk disagrees with the bowels, it may be boiled with roses, pomegranates, and cinnamon, with the addition of water. The fumigations advised by BENNET, change of climate, a voyage to Naples or Lisbon, are severally noticed with approbation. Dr. BRYAN ROBINSON praises emetics, especially those with ipecacuanha, in hæmoptysis, and adduces evidence of their effects. Dr. HORSBURGH gives some cases showing the benefits produced by the aluminous chalybeate spring, the Hartfell Spa near Moffat, at an advanced stage of consumption.

263. Dr. GILCHRIST adduces numerous cases showing the great advantage accruing from seaweeds. He considers hæmoptysis a conse-

quence of tubercles previously existing, and remarks that there are still tubercles to be resolved, even after ulceration has taken place, and hence the difficulty to give appropriate remedies for every stage in which tubercles may be found. But sailing and sea-air appear the best calculated to fulfil all the indications. On a rocky coast, where the inhabitants live much on shell-fish, he observed consumption decidedly more rare than in the country inland. He considers that the practice in this disease should consist in a proper administration of bleeding, issues, mercurials, balsams, diet, sea-voyaging, and sea-air. The practice of Dr. MARRYAT has been very generally adopted, at least in many of its parts, until modern times. He strongly objects to bleeding in consumption, and recommends a nourishing diet, especially of pork broth, and exercise on horseback, but, above all, the "dry vomit," consisting of a grain of tartar emetic, with three of ipecacuanha, to be taken fasting twice or thrice a week, without drinking after it. If there be diarrhœa, he directs a grain of sulphate of copper with four of ipecacuanha. If ulceration exist, he gives twenty drops of copaiba in sugar night and morning. For hæmoptysis he gives his emetics in increased doses. Bark, nitre, sulphur, chermes mineral, and alum are also severally employed, according to circumstances. For scrofula he prescribes corrosive sublimate, with the addition of a few drops of the hydrochloric acid, &c.

264. There are few topics connected with the treatment of phthisis more important than that respecting the employment of opium, and to this TRALLER has devoted much attention, in a prolix and discursive work, in which the general treatment of the disease also is fully discussed. He considers opium to be useful in the first stage, but to be injurious afterward. He thinks that it is not even a palliative. He, however, gives it in enemata with decoction of bark and milk, for the palliation of the colliquative diarrhœa, and admits that it is useful in small doses when the cough is violent, for which also he gives the sirup of poppies. He recommends PLUMMER's pill, ammoniacum, soap, squills, and honey, milk diet, milk with lime-water, emulsions, and farinaceous substances. The works of MORGAGNI furnish no precise information as to either the morbid anatomy or the treatment of pulmonary consumption, beyond what was previously known. Of the other contemporary writers on medicine there is none who gives any information respecting the treatment of consumption deserving notice, until we arrive at the works of Sir JOHN PRINGLE, DONALD MONRO, and others.

265. The observations of Sir JOHN PRINGLE deserve the high estimation in which they have always been held. In recent coughs he gives, after bleeding, mucilages, oils, and ammonia, in the form of an emulsion; and at night laudanum with oxymel of squills, or gum ammoniac. When the symptoms assume the form of hectic, he repeats the bleeding, recommends low diet, and the employment of setons or issues, which he justly considers still more beneficial than bleeding. If thirst or heat be great, acidulated drink, or buttermilk, without animal food, are advised. To check the sweats he uses sulphuric acid, or lime-water, conserve of roses, air, exercise, a milk and vegetable diet, and where there are debility and lowness of spirits, the bark is recommended. DONALD MONRO appears to have adopted the

practice of PRINGLE in phthisis. He has recourse to bleeding when there is pain, and to cinchona when neither pain nor difficulty of breathing is experienced. Setons and issues, he says, are always of use. A gentle emetic is advised for difficulty of breathing. For diarrhœa rhu- barb and afterward opiates are given.

266. LIEUTAUD, in his *Synopsis of Medical Practice*, considers bleeding injurious, and advises chiefly a milk diet, with pectoral decoctions, balsams in small doses, sulphur, tar-water, or MORTON'S balsamic pills, the fumes of balsamic herbs, the waters of Bonnes or Seltzer, or lime-water mixed with milk, riding, issues between the shoulders. For the consumption produced by hard study, he prescribes camphor with HOFFMANN'S anodyne, baths, frictions, change of air, horse-exercise, and generous wine. LINNÆUS suggests the use of the lichen pulmonarius in phthisis. The Lichen Islandicus was known to earlier writers, according to Dr. YOUNG, although it is not mentioned by LINNÆUS. Mr. READ lauds a residence in a cow-house in cases of consumption, and says that it is preferable to any fumigations. The recommendation of a medicine called the decoction of a thousand flowers, which was much used from two to three centuries ago for the different forms of consumption, is more rational than this singular residence. This decoction, or infusion, as sometimes prepared, was made from the recent dung of cows while feeding in open pastures, warm or cold water being mixed with it, and allowed to stand a considerable time, and the clear fluid being poured off for internal use. The bile existing in the dung was thus partially extracted, and employed as a stomachic.

267. The works of HEBERDEN, SAUVAGES, and FOTHERGILL furnish no additions to the method or means of treating phthisis already known. STORCK is extravagant in his praises of hemlock in this disease. VAN SWIETEN, in his commentaries on the aphorisms of BOERHAAVE, observes that persons exerting their voice in their professions are more liable to hæmoptysis than others; and that MOLIERE died of an attack of this disease immediately after performing his "Malade Imaginaire" for the fourth time. He believes in the communication of phthisis by infection, and considers that an hereditary disposition to the disease does not necessarily imply its actual existence. He approves of camphor as prescribed by AVICENNA (§ 247), and of the treatment adopted by PRINGLE. He praises the use of milk, small but frequent bleeding, horse-exercise, the cautious employment of cinchona, and of opiates. For relief of the diarrhœa, he directs an enema of a drachm of turpentine, rubbed down with yolk of egg, adding half an ounce of theriac and four ounces of new milk. The treatment recommended by MACBRIDE is, in most respects, the same as that already so frequently noticed, namely, gum ammoniac, soap, and ammoniacal iron, early in the disease; gentle emetics to promote expectoration and relieve dyspnœa; bark, in some cases, goats' whey, asses' milk, buttermilk, Seltzer, Bristol, or Malvern waters; riding, and especially sea-voyaging, setons, or issues, &c. For hæmoptysis, he directs bleeding, opiates, and demulcents. WINTERINGHAM disapproves of fumigations, as prescribed by BENNET and MEAD, but thinks that the steam of hot water containing vinegar of squills may be inhaled with advantage.

268. Dr. JAMES SIMS, the founder of the Medical Society of London, is favourable to emetics, to sulphur, and to cinchona, suitably employed. Tar-water is also useful, but he considers tar pills to be preferable. The following remarks are correct: Females not uncommonly have a respite from consumption when they marry, but sink under the disease after having had two or three children. The catamenia may remain natural till the last stage, but this, I may add, occurs only occasionally, and chiefly in the more chronic and protracted cases. SCHOENHEYDER employs the decoction of Iceland moss, especially in phthisis consequent on measles, or after the removal of inflammatory symptoms. TONE very judiciously gives the bichloride of mercury in the infusion of cinchona, with Iceland moss, and a milk diet, in syphilitic consumption. Dr. MOSES GRIFFITH is deserving of notice, chiefly for his recommendation of chalybeates in consumptions, and more particularly for his *Mixtura Ferri Composita*. This mixture is, however, varied by him according to the circumstances of the case; adding nitre in young subjects and recent cases, myrrh at a more advanced stage, and when there is more debility. He farther advises a diet of asses' milk, or skimmed milk, puddings, rice, potatoes, and a little light animal food, once a day, and, above all, snail-broth, or snails boiled in milk. LINNÆ reports favourably of the *Hypericum perforatum* in hæmorrhagic and ulcerous phthisis, a handful of the tops of the plant being made into a decoction with Spanish wine, boiled down to one third, and an eighth taken morning and evening.

269. The treatment adopted by CULLEN for phthisis was generally followed in this country until early in the present century. When expectoration of purulent matter, with hectic fever, is present, he believes that ulceration exists. He views catarrh as rarely a cause of phthisis in persons not predisposed to this disease, but it ought not to be neglected. Spasmodic asthma not unfrequently terminates in phthisis. In two cases of the expectoration of chalky concretions, the patients recovered by the aid of milk diet, &c. Consumption from hæmoptysis is less universally fatal than other forms. "Hæmoptysis is not always followed by ulceration, nor is ulceration always attended with hectic. Pregnancy retards the symptoms, but they generally recur and become fatal soon after child-birth." In the hæmorrhagic form of the disease he thinks the acetate of lead dangerous, and chalybeates and cinchona improper, as tending to increase the phlogistic diathesis, and as having been found injurious in his practice. He prefers evacuations of all kinds, a low regimen, and blisters to the breast or back, followed by issues. Sea-water and other mineral waters are wholly useless, and mercury is prejudicial. Milk is a chief remedy; and violent exercise, and the extremes of cold and heat, are to be avoided. He thinks that sea-air is desirable only for its moderate temperature; that the balsams, myrrh, &c., have sometimes done harm; that bark increases the phlogistic diathesis, and even when it relieves for a time, the symptoms speedily return; that acids are useful, especially vegetable acids; that opiates are necessary for allaying the cough, but they often increase the sweats; that demulcents frequently disagree with the stomach; that the diarrhœa requires astringents and mucilages, and that all purgatives are dangerous, but ripe fruits are often both agreeable

ble and beneficial. M. BRILLONET records cases illustrating the connexion of tubercular phthisis with scrofula, and the successful treatment of the former by small doses of corrosive sublimate, and by a diet of soup, eggs, and vegetables.

270. STOLL offers some judicious observations, although others are more open to objections. For tubercular hæmoptysis he advises small and repeated bleedings; gentle emetics; acid and nitrous drinks, and afterward lichen, polygala senega, or cinchona. For hectic diarrhœa he gives the powder of the root of arnica. He disapproves of balsams, bark, and astringents, where there is any inflammatory complication. BERGIIUS strongly recommends the Iceland moss in phthisis. When its tonic qualities are not required, he directs the bitterness to be extracted by previous maceration. Dr. MUDGE employs the inhalation of medicated vapours for consumption. He believes hæmoptysis to result from the obstruction caused by tubercles; and for this state of the disease he advises nitre in solution, a moderate bleeding, and emetics; for cough, the inhalation of emollient vapours, the ammoniacum with laudanum, or half a drachm of the anisated balsam of sulphur, a very large scapulary issue, if these fail, and a milk diet and vegetables. He reprobates the use of small issues, and advises them to be large and efficient—a recommendation agreeable to my experience.

271. Dr. SIMMONS notices the form of consumption produced by dry-grinding, or by breathing the minute particles of sandstone and iron. He considers the practice of bleeding to have been carried too far by DOVER. He prescribes nitre and camphor, myrrh with spermaceti; and oranges and ripe fruit in preference to sulphuric acid. Setons and issues, he says, are useful, opiates mischievous, and ripe fruit and antiseptics are the best remedies for diarrhœa. A little animal food, plainly dressed, may be allowed if much desired. Change of air is advised; but he justly adds that migration to a warm climate, late in the disease, merely hastens death. Emetics of sulphate of copper, twice or thrice a week, in the early stage, preceded and followed by a draught of water, are also given with the vain hope of dispersing the tubercles. The observations of HOME, DUNCAN, and REID furnish little or no information. The last-named physician advised chiefly the exhibition of ipecacuanha emetics, morning and evening, and considered sea-voyaging beneficial, mainly by producing nausea and vomiting. Verily his treatment seems to have been as bad as the disease. BORSIERI again thinks emetics injurious, and balsamic remedies hazardous; but he approves of bark in incipient cases, of camphor, and of balsam of tolu and turpentine in advanced stages. POUTEAU advises, when pain is experienced, bleeding, and cupping, and blisters.

272. Dr. STARK's posthumous observations contain the earliest correct account of the anatomy of tubercles. He is favourable to bleeding in the early stages, to oleaginous and demulcent medicines, and to vinegar of squills, &c., when cough and dyspnœa are urgent. RACLIN's views as to the treatment of phthisis are in some respects heterodox. He is more correct in recommending ipecacuanha in the catarrhal complications of the disease. He considers gums to be preferable to emulsions; and the preparations of casearilla to be appropriate for the sweats and for diarrhœa. Sir-up of tolu with ptisans; and myrrh, camphor, and

a little opium every night, are very generally prescribed. He praises opium in large doses for hæmoptysis; and the mineral waters of Caunterets and Bonnes for convalescents. Dr. WITHERING, in 1785, in his account of the foxglove, notices the recommendation of this medicine by Mr. SAUNDERS in consumption, and states that he found it of advantage in several cases when it was given in a decided manner. Dr. DARWIN, however, is doubtful of its good effects; and Sir G. BAKER is of opinion that its influence in phthisis is owing to the sickness it occasions.

273. Sir G. BLANE considers the best climate for the consumptive to be between 30° and 40° north latitude. VOGEL prescribes the vegetable acids with gum arabic; and, for phthisis after fevers, the taraxacum, bitter extracts, and horehound, or the cold infusion of cinchona with rhubarb, if inflammatory symptoms be absent. The cold infusion of bark he gives most frequently with acids or nitre, or made with whey, and preferably during the remissions of the hectic. He agrees with SIMS as to the use of oysters as an article of diet. QUARIN considers emetics unsafe in phthisis; he gives bark with sulphuric acid for the sweats; Spa water with milk in preference to Seltzer water; and the senega when the expectoration is difficult. Dr. MOSELEY believes that England furnishes change sufficient for an invalid; but that a voyage to Madeira early in the disease may be of advantage. For hæmorrhagic phthisis and pulmonary oppression he prescribes a vitriolic solution with the sulphates of zinc and alumina as an emetic, instead of bleeding, followed by a sea-voyage.

274. Dr. MAY states that, in a well-marked case of phthisis in a young person of a scrofulous constitution, the patient took laudanum night and morning, an ipecacuanha emetic when the stomach was loaded, and cinchona; and that the diet consisted of soup, meat, wine, porter, brandy and water, eggs, oysters, &c., with proper condiments. Swinging was employed twice daily, and horse-exercise completed the cure. A similar case was published by Dr. KENTISH. I recollect meeting Dr. MAY in 1820. He argued strongly in favour of his tonic and nourishing method of treating phthisis, which then appeared heterodox, but which is now more or less adopted. Dr. GRIEVE notices his employment of koumiss, a fermented liquor made from mare's milk, in the early stage of phthisis. The fermented whey of cow's milk is used as a popular beverage in this disease in Norway and the Shetland Isles. Dr. CRICHTON gives a favourable report of the Iceland moss in cases of phthisis uncomplicated with inflammation. BANG, of Copenhagen, recommends the oil of asphaltum, in doses of eight drops morning and evening in rye broth. The pneumatic treatment, first tried by FOURCROY, and more fully discussed and employed by BEDDOES, furnishes no satisfactory results. Dr. SENTER, of the United States, prescribes emetics of ipecacuanha and sulphate of copper, every second or third morning, without eating or drinking, and as much of GRIFFITHS's chalybeate mixture (§ 268) as the stomach will bear in the intermediate time. For children especially, the sulphate of zinc is a preferable emetic. A milk diet is also directed.

275. The first volume of the "Medical Inquiries" of Dr. RUSK, of Philadelphia, contains some of the most important observations on consumption which appeared towards the close of the last

century. He was himself subject to consumptive symptoms during a considerable portion of his life—a circumstance which imparts additional weight to his advice. He recommends, upon the first indication of the disease, or as soon as heat in the hands, weakness of the eyes on wakening, dryness of the feet, inactivity, and other slight febrile symptoms appear, the patient to have recourse to a more active life, with bathing, bark, and steel. When the pulse is hard, with pain or bloody expectoration, he directs frequent bleedings, and where bleeding cannot be employed, emetics and milk diet. In the last, or typhus stage, as he terms it, he considers that a temporary benefit is derived from balsams, horehound, vegetable tonics, bitters, cinchona, &c., the diet being now stimulating and nutritious. He believes damp situations injurious in all states of the disease, and a high, dry, and temperate residence in the country most beneficial. He advises also flannel always to be worn next to the skin, the dilute vapour of tar, or the smoke of resin to be inhaled, opiates to be given in small doses during the day, and more largely at night, and repeated blisters and small issues to be employed. He admits of a moderate exercise of the lungs in speaking, reading, and singing; and a gradually increased exercise of the body, especially of the limbs.

276. Dr. GREGORY, of Edinburgh, in his lectures considers mercury injurious; cinchona of little use, and myrrh of less. The mineral acids he views as palliatives only, and as inferior to the citric acid. Emetics are sometimes useful, even without operating powerfully; sulphur is liable to be too laxative, but beneficial nevertheless; and purgatives hazardous as either inducing or aggravating the diarrhœa. Dr. FERRIAR finds digitalis with change of air of service in the mucous consumption (chronic bronchitis), and in checking incipient phthisis, when the patient is too weak to bear evacuations. The pneumatic means, so much and so sillily vaunted at that time, and like other means puffed, with their authors, into undeserved notice much more recently, he justly considers quite undeserving adoption. Dr. GARNET introduced several chemical medicines into practice about the end of the last century. He prescribes the sulphuret of potass, and powdered charcoal, in the florid states of consumption, and gives a drachm of each of these, four or five times a day, in warm water, with the effect of promoting expectoration and improving the other symptoms. I question, however, the ultimate good arising from medicines which “promote expectoration,” as I have too frequently seen them promote other more unfavourable symptoms.

277. In the writings of DARWIN, in which there is a mingling of hypothesis, fancy, and poetical imaginings, with ill-assorted experience, I find nothing on the treatment of phthisis deserving notice, or at least nothing worth attention which had not been previously advised by many of his predecessors. J. FRANK professes himself an advocate for the tonic and nutritious treatment in phthisis proposed by SALVADORI, MAY, and others, though with much more moderation in the degree; palliating the urgent symptoms by opium, and endeavouring to relieve the debility by cinchona, lichen, milk, wine, exercise, and nutritious food—a treatment, however, by no means admitting of general adoption. Dr. BARTON men-

tions the *Arum triphyllum* boiled in milk as a remedy in phthisis, states that he has known only of one case of the disease cured by digitalis; and that he finds more benefit from emetics of sulphate of zinc than from other means.

278. Dr. FOWLER and Dr. FERRIAR relate cases of consumption cured by digitalis given as decoction or infusion; but it is not improbable that more benefit was imputed to the medicine than it really deserved, as most of the cases were characterized chiefly by hæmoptysis, and as those are often attended by prolonged periods of amendment. That it is, however, followed by some degree of benefit, especially early in the hæmoptysical form of the malady, appears from the testimony of BEDDOES, MOSSMAN, MACLEAN, SHERWEN, and others, although this position is denied by Dr. BREE. Dr. MAGENNIS's success with digitalis may be attributed chiefly to the very large doses, and to the early period of the disease in which he prescribed it. BUSCH in his researches employs chiefly aconite, hemlock, henbane, and dulcamara, combined with either ipecacuanha, chermes mineral, or honey of squills. He prefers the leaves of aconite to the extract, and gives two grains every two hours, increasing the dose to a drachm daily. Dr. BEDDOES insists upon the propriety of confining the phthisical patient to a temperature varying only from 60° to 65°, and believes that the muriate of lime is sometimes of service.

279. Dr. HEBERDEN considers asses' milk to be of use in allaying the fever; decoction of bark and sulphuric acid in relieving the sweats; opium in quieting the cough and favouring sleep; bleeding to the amount of five ounces only, when pain is urgent; and the application of a blister when the pain is obtuse. He advises a vegetable diet chiefly, and the purest water for drink. Dr. THOMAS recommends an emetic every second or third day, especially in the early stage, GRIFFITH's iron and myrrh mixture, and digitalis. Dr. TROTTER is favourable to cinchona and sulphur; and to digitalis with opium. Dr. WILSON considers sulphuric acid to be most efficacious in checking the sweats; and a demulcent mixture with spermaceti and a little laudanum most useful for the cough. He allows animal food in moderation; and the vapour of warm water, in which onions have been boiled, to be inhaled in order to facilitate expectoration. Dr. BOURNE furnishes experiments on the use of the *uva ursi* in consumption, from which he infers it to be of service early in the disease, in doses of ten or twelve grains, twice or thrice daily, sometimes taken with a small dose of opium. The end of the last century and the commencement of the present abound with writings on the treatment of phthisis, many of them most inconclusive, some of them trifling or puerile, and nearly all of them deficient in precision of description, and in logical inference. Most of these are filled with discussions and cases proving and disproving the efficacy of digitalis, and commenting upon the operation of this medicine.

280. Dr. BADHAM, in 1808, was the first to distinguish between asthenic and chronic bronchitis and tubercular phthisis, the former having been generally viewed as varieties of pulmonary consumption, and thus confounded with the tubercular disease. A large proportion of the recoveries of cases which had been considered tubercular, was evidently cases of bronchitis. Several writ-

ers at this period added nothing to our knowledge, or placed before us the "crambe bis coctum," or rather decies coctum, of their predecessors. RUSSELL expresses a favourable opinion of bark, calumba, chamomile, sulphuric acid, and iron, with hemlock. But these require discrimination as to the cases in which they may be individually prescribed. He considers the virtues of hemlock to be much overrated. Both he and THOMSON state the muriate of lime to be without any efficacy. In the more purely scrofulous phthisis, he considers issues to be decidedly beneficial, and sulphuric acid and salines as preferable to cinchona in the early stage. BARTON and others in America employ the super-acetate of lead with ipecacuanha and opium in the hæmoptysic form of phthisis.

281. The remarks of Dr. PARR are upon the whole judicious. He advises the pain in phthisis to be pursued by blisters as it changes its place; emetics to be given chiefly in hæmoptysis, and without informing the patient, ipecacuanha being preferred; and mild diaphoretics in an early period. He considers balsams of use only when expectoration is checked by debility; myrrh occasionally of service as a slight tonic and sedative; hemlock to be preferable to opium in palliating the cough without occasioning sweats; cicuta and the seeds of hyoscyamus to be often useful; and digitalis to do more harm than good. Asafetida is recommended for flatulency and as an expectorant. In the last stage, emetics and other means are quite inefficacious, or palliatives merely. The work of PORTAL, although interesting at the time when it appeared, contains very little of importance in respect of treatment. He considers the mildest food the best, and particularly new-laid eggs; and issues, setons, and moxas, of service. Dr. BUXTON furnishes additional evidence to that adduced by BEDDOES in favour of a regulated temperature in phthisis, of from 60° to 65°. Dr. SHEARMAN notices the connexion of consumption with amenorrhœa, and observes that GRIFFITH's chalybeate mixture has been more successful in females than in males, owing to this connexion. There is much truth in this: early in the disease this mixture is advantageously conjoined with the compound decoction of aloes and conium, and even in more advanced stages, if it do not increase the severity of the cough.

282. M. BAILEY very justly referred many of the cases of imputed recovery from phthisis to the circumstance of chronic bronchitis, or chronic pulmonary catarrh having been mistaken for phthisis; and he described, with greater precision than heretofore, the structure of the tubercular deposits, and the pulmonary and the associated lesions. The granulated form of this writer is merely the earlier stages of the disease, excavations not having taken place. In this state he advises, according to the features of individual cases, composing and emollient medicines, occasionally bleeding, blisters, and issues; aconite, hemlock, henbane, nightshade, and opium, and, where the expectoration is very copious, balsamic and resinous medicines. In the state of ulceration, he employs medicated vapours and external drains and revulsants of various kinds. In cases complicated with chronic bronchitis or catarrh, the lichen, with diaphoretics and balsams, is prescribed; or with bark, when there are well-marked rigours. Streaks of blood in the expectoration require lemonade or orangeade, and bleeding if the pulse be hard; blisters, if soft. As pro-

phylactics, he recommends travelling, voyaging, change of air and climate, nutritious diet, antiscorbutics, tonics, alkalies, muriate of ammonia, &c.; for incipient cases, repeated emetics, bitter and stomachic purgatives, a sea-voyage, exercise, the sulphuretted waters of Bonnes, Cauterets, Bagnères, or Mont d'Or; and later in the disease, mild tonics, as the lichen, sirup of cinchona, &c.

283. Dr. WELLS contends that phthisis is much less prevalent in marshy countries and districts where agues are endemic, and advises that consumptive patients should be removed, at least for some time, to these places. He quotes several authorities and statistics, by both which the subject is placed in exaggerated points of view. It is not yet satisfactorily proved that malarial situations are beneficial in either the early or the advanced stages of phthisis; at least the matter should be farther investigated, as well as the assertion that places wherein ague is endemic are free, or nearly free, from phthisis; inasmuch as the position is controverted by several more recent writers, although contended for by MARSHALL, WEEKES, HARRISON, and others, towards the close of the last century and at the commencement of the present.

284. Dr. ROBERTS has endeavoured to discover a more effectual remedy for consumption among the active mineral salts and other substances, than those hitherto employed. He has, however, only to record the failures of his experiments, with the nitrate of silver, superacetate of lead and opium, sulphate of zinc, oxyde of zinc, alone or with myrrh; white oxyde of manganese (10 grains); arsenite of potass; black oxyde of cobalt (one to four grains); ammoniated copper, muriate of baryta, nitric acid, phosphoric acid, aconite, henbane, stramonium, belladonna, and toxicodendron.

285. Dr. A. DUNCAN gives the results of his long experience in the treatment of phthisis. He considers hæmoptysis as often a salutary occurrence early in the disease; bleeding with low living to have hastened death in many cases; emetics to be of use in promoting expectoration, but to be useless as respects the cure of the disease; and blisters to be of service in most forms of the malady. He believes that vegetable acids are more beneficial than the mineral or acetous; that digitalis is of little use, and sea-voyages are counteracted by the inconveniences and risks attending them; that bark, myrrh, lichen, or these with hemlock, are sometimes of service in scrofulous cases, but that the pneumatic practice is altogether unsuccessful; that the diarrhœa may be moderated by mucilaginous fluids and broths, melted jellies, rice, catechu, opium, &c.; that the inspissated juice of the common lettuce is one of the best substitutes for opium, and that the patient should take asses' milk, wear flannel next to the skin, and have walking and riding exercise. Dr. SOCRNEY has remarked upon the frequency and infrequency of phthisis in different countries. He is in favour of the use of issues, of digitalis for hæmoptysis, of a regulated temperature, by means of a stove, from 60° to 65°, of riding, sailing, and swinging, and of change of air, at an early stage, to Valencia, Hières, &c.

286. Dr. THOMAS YOUNG, in his able and learned work on Consumptive diseases, has given an interesting account of the treatment of these diseases, and a full digest of the means employed for this purpose in this country during the first quarter of the present century; and until the di-

agnostic method of LAENNEC and the pathological and numerical disquisitions of French writers allured the minds of practitioners to the neglect of rational therapeutical doctrines. Dr. YOUNG considers *bleeding* an important remedy at an early period of the malady, for the removal of inflammatory and congestive symptoms, and for obviating the suppuration and debility consequent on them. From six to twelve ounces of blood, he remarks, may be taken away with safety in every incipient case, and the operation may generally be repeated with advantage three or four times, at proper intervals; but to do more than this might justly be called an experiment which, however laudable in proper circumstances, is not to be recommended in the ordinary routine of practice. Dr. YOUNG was himself bled twice, by the direction of his uncle Dr. BROCKLESBY, and was in favour of small bleedings, to the extent of three or four ounces—locally, when there is pain in any part of the chest. He advises *purgatives* at an early stage, and considers that fears of promoting the diarrhoea by them at this period should not be entertained. He justly views *sulphur* as an excellent aperient in the disease, and especially when complicated with hæmorrhoids. Dr. YOUNG also recommends *emetics*, and prefers *ipæacuanha*, especially in cases of hæmoptysis, combining it with acetate of lead or other means, according to circumstances. On *sorbefacients*, especially *digitalis*, *mercurials*, and *alkalics*, he places very slight reliance, although they may be prescribed in some circumstances of the disease with advantage. *Epispastics* and *issues* are viewed by him much more favourably. He considers that the tendency to night sweats is not a just reason against the use of *sudorifics*, especially DOVER'S powder and antimonials. In *expectorants* he has little faith, although *ammoniacum*, *squills*, *senega*, *myrrh*, and *ipæacuanha* may be employed with benefit in some cases, in conjunction with hemlock and other *palliatives*. *Dennulcents* and *narcotics* are prescribed by him in circumstances indicating their use, sometimes with balsams, the benzoic acid, &c. Of *astringents*, when required to moderate the secretions of the skin and of the intestines, the sulphuric acid is considered the best, especially when conjoined with aromatics and opiates; but he is also in favour of catechu, kino, the extract of logwood, with chalk mixture, or the compound powder of chalk.

287. Dr. YOUNG believes *cinchona* to be the most important *tonic*, and both its advantages and inconveniences to have been exaggerated. He has known it decidedly beneficial at the commencement of the disease, and he has never observed that it increased the hectic symptoms at any period. Besides the powder, and the decoction, he has employed the cold infusion with Seltzer water, in his own case, as well as in others. He has had little experience of *chalybeates*; but he justly remarks that, when they can be taken alone, or with myrrh, as in GRIFFITH'S mixture, without increasing cough or pain—effects which may also proceed from cinchona—they are sometimes beneficial. The *diet* most favourably mentioned by Dr. YOUNG consists chiefly of milk and the farinacea, especially asses' milk twice daily, cow's milk boiled with soda-water or lime-water, butter-milk, new eggs, vegetable and farinaceous articles. He has found milk boiled with mutton suet of great service. *Exercise* in the

open air, riding, walking, &c., are also severally advised. *Change of climate* is recommended, and he considers that the remark of CELSUS, that the worst air for the patient is the air which has given rise to the disease, is founded on good sense.

288. I have now brought down the *Historical Sketch* of the treatment of phthisis to a sufficiently recent period. Notices of some more modern writers will appear in the sequel only in so far as they may furnish any thing deserving notice. Their works will, however, be mentioned in the *Bibliography* and *References*; so that the reader may be aided in satisfying himself as to the views of those who have written on this difficult subject, or on topics appertaining to it. I shall next endeavour to state those means of prevention which seem most efficacious against this malady, and afterward proceed to give the results of my experience as to the means which appear to me the most appropriate, or which have been advised for the several stages and states of this disease, conformably with the division above adopted (§ 17, 76, et seq.).

289. ii. OF THE PREVENTION OF PHTHISIS.—The full exposition of the *causes* of phthisis which I have given above, and which many readers may consider tedious and unnecessary, will not be viewed in this light, when it is admitted that a knowledge of these causes, and of their modes of operation, is the most certain basis of rational means of prevention. By ascertaining the causes, and the ways in which they act, as far as they may be ascertained, we are enabled either to avoid or to counteract them. When we can neither avoid nor arrest the causes, we should endeavour to arrest or to palliate their effects, by means rationally selected and employed—guided by the lights of science, and by careful observation and induction. The great objects, therefore, of treatment are, in the first place, to avoid and to counteract the causes of the malady; and, secondly, when this end cannot be attained, to arrest or palliate their effects. The former constitutes the *prevention*, the latter the *cure*, of the disease. But in the procession of morbid conditions from the first impression of the causes, there is an intermediate state between the operation of the causes and the development of their effects in a manifest form, that requires the prompt recognition of the physician, and rational decision as to treatment. This state of incubation—of threatened or incipient phthisis—requires great acumen for its detection, and equal promptness for its arrest. For this state *measures of prevention* should be conjoined with *means of cure*, either predominating according to the circumstances of individual cases.

290. The *prevention* of phthisis is either *radical* and *efficient*, or *conditional* and *uncertain*. The avoidance or removal of the causes is required for the former; the counteraction or the arrest of their more immediate or early effects is all that can be expected from the latter; the one is *positive*, for the causes have not existed or acted; the other is *contingent*, for the causes have been present, have probably acted and produced their more immediate effects, the means of counteraction or of arresting these effects either succeeding or failing, as numerous circumstances may determine. Prevention thus may be divided into, first, that which consists of the avoidance of all the causes of the malady; and, second, that which attempts the counteraction, or the removal

of their more direct and immediate effects, before the malady is fully developed.

291. *A. The efficient prevention of phthisis* consists in the avoidance and removal of the causes which predispose to, and directly occasion, the malady. Those which affect one or both parents, or which operate during the earliest epochs of childhood, have generally produced their effects upon the constitution before professional advice is obtained. The transgressions of the parent have already injured the offspring, and the scrofulous taint has either been communicated to, or generated in, the child, before efficient measures of prevention could be instituted. The remarks which I have offered on the prevention of SCROFULA (see § 148, *et seq.*) apply with equal, if not greater, force to the prevention of phthisis. Consumptive persons who marry are even more culpable in this than those who are imbued with the scrofulous diathesis, or who have been affected with external tuberculosis. The offspring of the former may be scrofulous, but the taint is more likely to be manifested in the form of tubercular consumption, while the offspring of the latter are more liable to external tuberculosis, although they may be attacked with phthisis, especially when the external malady has not occurred. When the *predisposition*, whether it be hereditary or occasioned by the habits or the diseases of the parents, or by the management of infancy and childhood, has been produced, the radical and complete prevention of the malady can then rarely be effected, the best efforts to this end being merely conditional or uncertain. It is only by the avoidance of those causes which I have arranged under the head of *Causes appertaining to one or both parents*, aided by the removal of those which usually act during the early epochs of life, that the efficient or certain prevention of this disease can be expected.

292. *B. The conditional prevention of phthisis*, although uncertain, should not be neglected. Where the predisposition, arising from either the constitution or the health of the parents, already exists, prevention may be hoped for, but it cannot be insured.—*a. During infancy and childhood* the hygienic precautions which were offered when treating of SCROFULA (§ 148, *et seq.*) are even more urgently required when tubercular consumption has appeared in the family of either parent, or when the causes mentioned under the first class of the arrangement have injured the constitution of one or both parents. For children thus circumstanced, a dry, pure, and mild air, considerably elevated above the surface of the sea; frequent change of air; clothing suited to the temperature and season; exercise in the open air; light, digestible food, with strict attention to the digestive functions; a milk, farinaceous, and vegetable diet, with a moderate proportion of wholesome animal food, as childhood advances; but the milk of a healthy nurse, asses' milk, &c., during infancy, and the other means advised in the place just referred to, strictly avoiding the causes incidental to this period of life (§ 49, *et seq.*), are severally of great importance, especially when aided by such other means as the circumstances of individual cases will suggest.

293. *b. During puberty and adult age*, the causes of phthisis which have been noticed as most frequently operating in these epochs of life (§ 184, *et seq.*) should be carefully avoided, especially those which relate to schools, sleeping

apartments, &c. A strict surveillance ought to be instituted over youths of both sexes in order to prevent masturbation, and as soon as this vice is detected, its enormity should be represented to the delinquent, and measures taken to prevent the mental contamination from extending to others. The sleeping rooms should be well ventilated; but their temperature ought not to be much lower in winter than that of the sitting apartments, especially for the delicate and predisposed. For these a physical and mental regimen should be enforced, aided by proper food and clothing; by change of air, preferably to a warm, dry, and pure air; by chalybeates in forms suited to the peculiarities of the case; and, where the predisposition is manifest, by travelling to and in healthy, warm, or mild and dry countries, as Egypt, Syria, Upper Egypt, South of Spain, or north coast of Africa, &c.

294. These preventive measures are chiefly suited to the rich only; and to these especially hunting, riding, farming in a dry, elevated district, and field sports are remarkably beneficial. The selection of professions and trades for those who are hereditarily or otherwise predisposed to phthisis is attended by great difficulty. Agriculture and the out-door exercises which it involves are salutary to those who can adopt them. Gardening offers some advantages, but these are inferior to those furnished by other agricultural occupations. Poorer persons should become sailors and butchers; but the life of a soldier, even in the best circumstances, is very unfavourable to those in any way predisposed to phthisis. To such persons especially, and even to the most robust, several trades are most injurious. Sculptors, stone-masons, miners, millers, flax, wool, and cotton dressers and workers, weavers, tailors, bakers, milliners, dress-makers, and other needlewomen are severally more or less liable to phthisis in consequence of their occupations; and so liable are "dry-grinders," knife, fork, razor, scissor, and needle grinders to tubercular consumption and other pulmonary diseases, that it has been said by Dr. C. HOLLAND that about one fourth of those engaged in these occupations died every five years.\* (*See ARTS AND EMPLOYMENTS in relation to disease.*)

\* All nuisances, all dangerous and insalubrious establishments, especially in large towns, besides being productive of several other maladies, are liable to develop phthisis, especially in the predisposed. The government of this country has as yet paid little or no attention to the due regulation of these as regards the public health; but in France, as Dr. WALLER LEWIS has recently shown, these establishments are divided into three classes, and before they are permitted to be carried on, certain authorizations and formalities are indispensable. In the first class are placed those establishments that must be isolated from private habitations, but not necessarily from the outskirts of a town; in the second are included those factories which do not rigorously require their isolation from habitations, but which it is important not to allow until assurance has been obtained that the operations proposed to be carried on in them are executed so as not to be a nuisance to the neighbourhood, and not to cause damage. In the third class are such factories as may remain without inconvenience near dwellings, but which should be subject to the surveillance of the police.

As regards the effects on health of various professions and occupations, it is shown by M. LOMBARD that, in 1000 deaths, consumption had furnished the following proportions, viz.: Occupations with vegetable and mineral emanations, 176; with various dusts, 145; with sedentary life, 140; with work-shop life, 138; with hot and dry air, 127; with stooping posture, 122; with sudden movements of arms, 116; with muscular exercise and active life, 89; with exercise of the voice, 78; living in the

295. iii. TREATMENT WHEN PHTHISIS IS THREATENED.—When phthisis is imminent, the measures of prevention already noticed, conjoined with others of a more strictly medicinal kind, should be adopted, according to the predisposition, age, diathesis, and circumstances of the patient. The digestive and assimilating functions ought to be promoted by the usual means, and especially by change of air, by voyaging, by travelling in warm and dry countries, more particularly in those already mentioned (§ 293), by suitable clothing, and by attention to the temperature and ventilation of sleeping-places. The preventive and curative influences of districts where malaria and the diseases which proceed from this source abound have been insisted on by Dr. WELLS and several of his contemporaries. He states that it was common for the consumptive in Flanders to remove to the marshy parts of the country. In Minorca, where agues are endemic, consumption, according to Dr. CLEGHORN, is very rare. Dr. SEQUEIRA states, that in the marshy country of Alentejo phthisis is rarely seen. VOLNEY says that consumptive patients are frequently sent from Aleppo to the sea-coast, where intermittents prevail. Other instances are adduced by Dr. WELLS in favour of his opinion; and, although it has been controverted by several writers, yet I believe, from several facts with which I am acquainted, that it is not quite devoid of truth.

296. In this, as well as in other periods of the disease, the clothing, especially that worn nearest the skin, should be warm, and the best suited to the preservation of the functions of this part of the frame. With this object flannel ought to be worn during the night and day; and the dress in females should be sufficiently high to protect the upper regions of the chest and the neck. Close cinctures of the chest and steel supports in corsets are injurious. Due attention ought always to be paid to the digestive and excreting

open air, 73; with animal emanations, 60; and with watery vapour, 53. In manufactures the majority of workmen are affected with scrofula; this scourge marks the children and the youths with its scars, swellings, and deformities, and attacks more especially the weavers.

The women furnish more maladies and diseases than the men, partly owing to the comparative paucity of their earnings, from which it arises that the poor workwoman is ill-fed, ill-clothed, and ill-lodged. In one sense, indeed, not money, but the want of it, may be denounced as the root of all evil. So, in this case, "want is a bad adviser, and quickly triumphs over the weak resistance of a conscience without religious light to guide it." Debauchery, followed by excesses of all kinds, comes in to consummate the work of destruction commenced by distress. The worst occupations are those of needlewomen, or *couturières*, dress-makers, embroideresses, and *modistes*, from whose ranks the public women are largely recruited.

The separation of the sexes in work-shops is a measure imperiously demanded for the moralization of the working classes.

As to the healthfulness of employments much depends upon whether they are carried on in the open air or in confined air. Consumption is twice as frequent in the first as in the second case; the latter group comprising occupations carried on in vast spaces well aerated, and in others which confine the workmen in close localities. In the latter phthisis is far more prevalent. The action of dusts on the lungs is in the direct ratio of the volume, weight, and consistence of their molecules. The inhalation of coarse particles is less dangerous than that of dusts finely divided, which penetrate more easily into the last ramifications of the air-cells. Dusts from hard substances cause a far greater number of consumptive cases than dust from soft bodies, or of ordinary hardness. The specific gravity of the dusts does not affect in any marked manner the production of phthisis. The order of the respective fatality of dusts is as follows: viz., 1, mineral; 2, animal; and, 3, vegetable.—*Report*, &c., by Dr. W. LEWIS.

functions, and to the state of the uterine discharges, which are often more or less disordered in the states of the disease now being considered. In many instances cod-liver oil may be of service; in others, as well as in these, sulphuretted or chalybeate springs, or a course of the one following that of the other. For females, the mixture *ferri composita*, and the decoction *aloes compositum*, in varying proportions, according to the state of the bowels, are often of service, especially when the pulse is languid, the catamenia scanty or difficult, and when the cough is not increased or rendered hard or dry by these medicines. In these cases flannel drawers, in addition to the other articles of flannel clothing, and woollen stockings should be worn. In other circumstances, or when the natural secretions and excretions are not suppressed, the infusion, or a weak decoction, of cinchona, with a mineral acid; or other tonic infusions, with aromatics, &c.; or the tinctura *muriatis ferri*, either with or without the preparations of columba and an increased quantity of the acid, may be prescribed, and may even be made the vehicle on the surface of which the cod-liver oil may be taken. Confined positions of the body, the labours of the desk, and close application to either study or business, ought to be avoided, and a due restraint should be placed on the instinctive desires and passions. Mental and physical occupations ought to be pursued as much as possible in open and airy places and apartments, and in a temperature never lower than 60° nor higher than 70°; and should not be such as to fatigue, but such as moderately or pleasantly engage the mind and body.

297. In this state, as well as in the preceding, and more particularly when the predisposition is marked, or the tubercular cachexia manifest, warm or tepid salt-water bathing, or sponging the surface of the body daily with a warm, tepid, or cold solution of salt—the temperature and strength of the solution varying with the state of the patient and the effects produced—is often beneficial; but this practice should always be followed by rubbing the surface smartly with a rough towel, and by the constant use of flannel nearest the skin. Various medicated fluids or lotions have been advised as washes for the chest and neck, in the circumstances now being considered, as well as in the first stage of the disease. Of these, however, the most deserving notice are, a weak solution of the nitro-muriatic acid, a weak solution of the pyroligneous acid, and tar-water, varying in strength with the circumstances of the case. This last lotion has been employed only by myself, the temperature of it, as well as of the others, being varied according to the feelings of the patient and the state of the air. Friction of the surface also should always follow a recourse to either of these.

298. iv. TREATMENT OF THE USUAL FORM OF PHTHISIS.—*Treatment of the First Stage of this form.*—The imminence of tubercular consumption may be viewed almost in the same light as the commencement of this stage; and the treatment advised for the former is altogether applicable to the latter, with various additional means adapted or modified to the circumstances of individual cases. When this stage has commenced, as indicated by the symptoms (§ 187, *et seq.*), the question is no longer, Are tubercles already formed? This must be answered in the affirmative. But their development may be delayed or pre-

vented by judicious treatment; or their absorption may even be procured, although this is a doubtful or rare occurrence. The great principle of treatment in this stage, as well as when the disease is merely threatened (§ 295, *et seq.*), is to develop the powers of life, and increase the vital resistance to the farther advance of the malady, without producing or augmenting febrile symptoms: 1st. By diet and regimen—by hygienic means; 2d. By medical treatment. A selection of means belonging to each of these heads, appropriately to the peculiarities of the case, will frequently promote the assimilation of the chyle globules and of the colourless globules of the blood, by supporting or developing the powers of life.

299. *A. The food and regimen of the patient* are of the utmost importance in this stage.—*a.* The food has always been discussed, questioned, dogmatically prescribed, and often pertinaciously persisted in, according to the doctrines of the day and the views of prevailing authorities; and instead of accommodating it to the peculiarities of the case and to the effects produced by it, an indiscriminating mode of administering it has been too generally adopted. At different periods of medical history, and by different physicians, very opposite kinds of food have been recommended. Some have praised a milk diet; others farinaceous and vegetable food only; many a combination of both; some have allowed a large proportion of animal food; and even not a few have permitted the use of fat meats, and a rich, full, and nutritious diet. The praises of certain kinds of diet have often been accompanied by denunciations of all others. Thus the inexperienced, and those who treat a disease according to its name and not according to the successive pathological conditions it presents, are bewildered, and an important part of the treatment is adopted and applied not more rationally than if it were drawn by lot, or were the turn-up of the die. Now each of those kinds of diet, modified and added to, according to circumstances, is appropriate and beneficial when appropriately employed, and when aided by a regimen judiciously prescribed. The diet in this stage should always have strict reference to the regimen which the situation and circumstances of the patient permit, and especially to the locality, temperature, and air in which he resides; and both diet and regimen ought to be directed according to his temperament and diathesis, to the states of vital power and vascular action, as indicated by the pulse and by the febrile symptoms, and to the indications of existing local lesions.

300. When the disease is not ushered in by hæmoptysis, or by indications of active congestion, and especially when it is traced to depressing or exhausting causes, then a nutritious diet, animal food in moderate proportion, the white kinds of fish, boiled, with a squeeze of lemon, with little or no other kind of sauce, and shell-fish, especially oysters, may generally be adopted. The fresh livers of the cod, torsk, ling, haddock, and coal-fish, and the fresh oil of their livers, may be very beneficially used as sauce for these kinds of fish; or the oil may be taken in a more strictly medicinal form soon after a meal. In these and in similar states of the disease even richer and more nutritious kinds of food than those may be tried, and the effects carefully observed. I have often advised a frequent use of fat venison

in some cases, and the fat of lambs or of mutton boiled in milk in others, with much benefit. In cases where this stage is characterized by little or no acceleration of the pulse, by despondency, by a poor state of the blood, and by absence of sub-inflammatory or congestive symptoms, a dry and nutritious diet, or a more full and restorative diet; animal food, consisting of mutton, game, &c., and even wine or malt liquors in moderation, may be allowed, if exercise in the open air, especially horse-exercise, short of fatigue, be regularly taken.

301. For persons of a fuller habit of body, or more sanguineous temperament than those just referred to, and especially when oppression, or constriction, or pain at the chest, or a dry, hard cough is complained of, the diet should consist chiefly of milk and of farinaceous and vegetable substances, ripe fruits, &c., and the antiphlogistic regimen should be adopted in every respect; but it should not be carried too far, especially in the scrofulous diathesis. In these cases, local depletions, issues, and other derivatives, as will be hereafter mentioned, should be employed according to the state of the pulse and other peculiarities of the case. For these, buttermilk, whey, and skimmed milk are excellent beverages and aids to diet. After the more inflammatory and congestive symptoms are removed, and when issues or setons have commenced to discharge, then a more liberal and nutritious diet may be allowed, and the cooling, antiphlogistic, and febrifuge medicines hitherto prescribed may be changed for those which are more restorative, and more calculated to support vital power and to promote a healthy assimilation. In these circumstances the fish diet, as advised above (§ 300), may be first employed, and the more nutritious articles of food be afterward given with caution.

302. *b.* In this stage, *change of air, voyaging*, more particularly in latitudes from 30° to 50°, or from 10° to 15° or 30° in winter, in vessels possessing comfortable accommodations; *travelling* in temperate and warm climates, with due regard to the temperature and climate, and to season; residence in a warm and dry air, the elevation above the surface of the sea, and the degree of atmospheric dryness being such as the patient finds to be most beneficial; regular exercise in the open air, preferably on horseback, and short of much fatigue; are severally of manifest advantage. Exercise on horseback is, however, rarely of benefit to females, and is generally too exciting, and consequently exhausting to them; walking or driving in an open carriage being more beneficial. In all cases, extremes of temperature, and sudden changes or vicissitudes of temperature, must be avoided, even by those who are able to take active exercise, as well as by those who are much less able.

303. *Travelling*, at proper seasons and hours of the day, is generally beneficial, especially when the patient is able to travel on horseback. Travelling on land by other conveyances is less serviceable; although an open carriage, when the weather will admit, is little inferior to riding, especially in the cases of females. But when a close carriage is used, the patient should sit with his back to the horses; and when he travels by railway, this seat should always be taken, a sufficient ventilation of the carriage being always preserved.

304. *Tepid and cold-sponging*, and washing the

surface of the body, or the surface of the chest merely, with variously medicated lotions, have been advised in this stage; but, excepting with those already mentioned, or with the lotions, liniments, and embrocations about to be noticed, this practice is seldom of much service when this period is far advanced, unless exercise can be regularly taken in the open air, and flannel be constantly worn nearest the skin. It is, however, beneficial when employed as a preventive measure for the predisposed, and for those of a tubercular cachexia (§ 170, 171); and when adopted at the commencement of this stage, and followed by very active frictions of the surface.

305. *c. A winter residence* is of the greatest importance in this stage to patients in cold or temperate climates, for that residence should be selected which will admit of regular and daily exercise in the open air. But this is not the only consideration by which we ought to be guided. Elevation above the surface of the sea, a situation near the level of or close to the ocean, or removed at a distance from it, and frequent or prolonged voyaging on it, are severally topics which require to be duly considered. As to the last of these—*voyaging*—very well-founded expectations of success from it may be formed, if it be commenced in this stage, or before the second be far advanced, more especially in cases which have been attended by hæmoptysis at their commencement or early course, and if it be continued for a sufficiently long period. Voyaging in the Mediterranean or in the Atlantic between the degrees of latitude named above (§ 302), and preferably in the Pacific Ocean, especially when prolonged, either in naval cruisers or by repeated voyages, so as to avoid the winter and spring of this and other countries unfavourable to consumptive patients, deserves to be more frequently recommended than it has hitherto been. Now that the passage across the isthmus of Panama is easy, voyages thence, in various directions in the Pacific Ocean, may be made, and a return to this country effected in May or June.

306. Elevation above the surface of the sea, especially in warm climates, and when dryness of air is attained by elevation, is generally beneficial. Even in temperate climates, where elevation is conjoined with dryness, the diminished temperature which results is not so injurious as generally believed. The cold of Canada is by no means injurious to the consumptive, owing to the dryness of the air being great in proportion to the lowness of temperature. If such a residence admits of regular exercise in the open air, it may be salutary, although a warmer air, and an exemption from sudden atmospherical vicissitudes, may be preferred.

307. The only question connected with residence that remains to be considered is, whether preference should be given to a sea-coast or to an inland locality. This is a difficult question to answer; and judging from the indisputable advantages derivable from sea-voyaging, and the very frequent recommendations of places on the sea-coast by modern physicians as winter-residences for the consumptive, it may be inferred that these places are actually the most healthy. But this inference is neither logical, nor practically correct as respects phthisical cases. The benefit derived from voyaging depends chiefly upon uniformity of temperature and the motions of the vessel, aided by the influence of a pure

sea-air on the digestive and assimilating functions. Residences on the sea-coast furnish only two of these elements of benefit, in an imperfect manner, but they are altogether deprived of the third and that which appears to be the most important. We must therefore refer to the results of observation for a decision; and, as far as my experience enables me, I may state, where two localities, one inland the other on the sea-coast, possess equal advantages as to dryness of the air; as to annual, monthly, and daily ranges of temperature; and as to vicissitudes of weather, and facilities for out-door exercise, that the inland situation should be preferred.

308. Whatever be the locality adopted for the consumptive, or however the patient may be limited in his choice, exercise should not be neglected, in air and sunshine, while he is able to enjoy it; and the temperature of his sleeping apartment should not fall below 60° or rise above 70°. The advantages derived from stoves, when properly regulated, are shown by their preservation of the warmth of apartments at all hours of the night; but a due ventilation ought always to be preserved where they are the only means of keeping the temperature at a proper elevation. Having insisted upon regulation of *diet and regimen* appropriately to the pathological states of the case in this stage, and upon the advantages of *change of air, of travelling, voyaging, and of suitable residence* during the winter and spring months, the *means* which are more strictly medicinal are next to be considered.

309. *B. The strictly medical treatment* of the first stage of phthisis must depend entirely upon the diathesis, temperament, and habit of body of the patient, and upon the states of vascular action, of local lesion, and of vital power. The predisposing and determining causes should also be kept in view; for these should influence or even almost change our indications and means of cure.—*a.* In cases where vascular action is excited, or the pulmonary circulation is oppressed or congested, or where pain is felt in the thorax, or where hæmoptysis occurs without being very copious, neither anæmia nor vital exhaustion being remarkable, *bleeding* ought not to be either neglected or delayed. The only consideration is, in what manner may it be most advantageously resorted to. Venesection, unless the patient be robust or plethoric, is rarely required. Scarification and cupping are most frequently to be preferred, as the circumstances are few in which this operation may not be efficiently performed, and a due quantity of blood withdrawn in a very short period, the operation itself generally proving a salutary derivative. When the quantity of blood to be taken is small, and in certain complications, the application of leeches may be preferred.\*

310. The quantity of blood abstracted at one

\* [We are obliged to dissent from the opinion here expressed, that bleeding is occasionally proper in this stage of the disease. When we bear in mind that weakness and defective nutrition are its essential characteristics, and that cases of uncomplicated pneumonia, where hepatization is well marked, will frequently recover sooner and better without blood-letting, we cannot but call in question the expediency of resorting to this heroic remedy in tuberculosis. Hence, as BENNETT well remarks, the great effort of the practitioner, so far from diminishing the strength, ought to be to support it, and favour cell-growth and disintegration; then, when the blood is loaded with the effete matter thus introduced into it, to assist its excretion by means of diaphoretics, diuretics, and purgatives, according to circumstances.—Ed.]

time should be small, or at most not great. In the majority of cases it may vary from four to twelve ounces; this last amount being allowed only where the habit of body and circumstances of the case appear the most to require depletion. Time should be allowed to observe the effects of the first bleeding; and after a due interval, if the symptoms still continue, or upon the return of the indications for having recourse to it, the operation may be repeated. The amount and the repetition of the depletions should be determined only by the peculiarities of the case and the judgment of the physician. It will often be observed that even when bleeding appears to be required, it is but ill endured, although the quantity withdrawn has been small. When this stage is developed by the suppression of an acustomed discharge, as of the catamenia, or of hæmorrhoids, then the necessity of having recourse to vascular depletion is obvious, and that method of performing it which is most likely to re-establish the interrupted discharge should be adopted. Leeches may be applied around the anus when the hæmorrhoidal discharge has been suppressed; and beneath the groins when the catamenia are interrupted, difficult, or scanty; and, for both causes of aggravation, calomel, the preparations of aloe, and warm fomentations or the hip-bath, may be prescribed. The older writers advised bleeding from the feet when immersed in hot water, in cases of catamenial obstruction, and this mode may be adopted by those who prefer it. I have sometimes prescribed it, and seen it employed, with benefit.

311. Vascular depletion has been advised in the first stage of phthisis by some authors, and reprobated by others. I have now stated many of the circumstances which require it; but there are others, more especially certain complications hereafter to be noticed, which also are benefited by it. But cases are common for which, even at an early period, bleeding cannot be ventured on with safety; or, if employed at all, it can be prescribed only to a small amount, and in the immediate vicinity of parts which appear to require it. The numerous class of cases caused by the depressing and exhausting causes mentioned above (§ 192), by want, by misery, by debilitating discharges, by confinement and etiolation in factories, close apartments, &c., and by sedentary and ill-rewarded occupations—those cases which present anæmied, cachectic, discoloured, and debilitated appearances, or in which the pulse is either slow and beneath the healthy condition, or very quick, small, or soft, or when the blood is inferred to be thin and poor in red globules—are severally injured even by the smallest local depletions, unless they be prescribed for the removal of the pains occasioned by pleuritic complications, for which the additional and often more successful means hereafter to be noticed should be employed.

312. The indications for and against vascular depletion in an early stage of phthisis are, however, not always to be depended upon. While many are manifest, others may be doubtful. Much, therefore, should be left to the close observation, the enlightened experience, and the acumen of the physician, in the interpretation of these indications and the discovery of others. The season, climate, peculiarities of race, modes of living, and prevailing constitution and character of disease, the prevalence of a sthenic or an asthenic condition of morbid action, are severally weighed in his

mind before bleeding in any way, its amount and its repetitions are decided upon, and before other important means are prescribed. The prevailing constitution of disease, so much insisted upon by SYDENHAM, differs most remarkably in different periods of time. The sthenic constitution, so general in the first quarter of the present century, was changed to the asthenic in the second quarter, and this latter still appears to continue. The vital energies of the residents in large cities and manufacturing towns, especially in low situations, are weaker than those possessed by the inhabitants of rural districts and elevated localities; and these differences, with others manifested by individual cases, require due consideration when devising our indications and means of cure.

313. The necessity of having recourse to vascular depletions, especially to local depletions, when congestion, sub-inflammatory action, pain, the state of respiration or of cough, or other symptoms, require them, does not necessarily prevent the exhibition of nutrient and even of restorative means, more particularly when vital power appears depressed and vascular action is not much increased. Indeed, in large cities and manufacturing towns, these latter medicines, or even more tonic remedies, are often required, although local depletions are equally necessary for the local lesions. For these milder tonics, conjoined with sedatives and narcotics, as the infusions of cheyrcita or calumba, with hydrocyanic acid, or conium, or hyoscyamus, or the tinctura camphoræ comp., may be first prescribed, and be followed, according to the effects observed, by infusions or decoctions of a more tonic kind. When, with debility, a cachectic or an anæmied appearance is present, the preparations of iron may be given, commencing with the mildest. I have generally preferred the *mistura ferri composita*, with the extract or tincture of conium, or the powder or extract of liquorice; and, if the bowels be sluggish, and the catamenia be deficient, with a sufficient quantity of the *decoctum aloes compositum*, or tinctura aloes.

314. The effects of chalybeates of every kind require to be closely observed in this as in every other stage and state of the disease. This class of medicines are contra-indicated where any inflammatory complication exists, or where a tendency to hæmoptysis is observed, unless hæmorrhage has occurred to a large amount, when the *tinctura ferri hydrochlorici*, with additional acid and appropriate medicines, may be given in a suitable vehicle; but on all occasions the effects of chalybeates on the respiration and the cough should be strictly watched, and, if rendered more oppressed, difficult, or hard by them, they ought to be relinquished. I have often prescribed the iodide of iron, in sirup of sarzæ, or in other sirups, with conium, or some other anodyne; but I have not considered it more beneficial than GRIFFITH'S myrrh mixture, even in cases where the catamenia are deficient; and I have found it in some cases to aggravate the cough and tightness of the chest more than that mixture.

315. When the above medicines are either not indicated or prove inefficacious, the infusions of cinchona, prepared either with cold or with warm distilled water, may be prescribed with hydrocyanic acid, or with any of the preparations of conium or hyoscyamus; and it may be taken in milk in which a little of the bicarbonate of potash or of soda has been dissolved. When fe-

brile symptoms harass the patient, the liquor ammoniæ acetatis may be given with the infusion of cinchona, and the spirit of nitric ether and hydrocyanic acid added to them. In some instances the liquor ammoniæ acetatis may be prescribed with an excess of acetic acid, especially where hæmoptysis occurs; and in others, particularly where sinking or exhaustion is present, with an excess of the carbonate of ammonia, other substances which the symptoms will suggest being also added.

316. In this early period of phthisis the functions of digestion—of both stomach and liver, are often more or less impaired; and it is often beneficial to them, as well as to the state of circulation in the lungs, to commence the treatment with an *emetic*. The older writers recommended this practice, and experience has shown that, when the emetic has been judiciously selected, and the treatment otherwise appropriate, benefit has been produced by it. The Italian physicians, and after them LAENNEC and his pupils, prescribed tartarized antimony as an emetic in this disease, having, as they believed, derived great advantage from it in the more strictly inflammatory diseases of the lungs; and not only did they employ it as an emetic, but as a contra-stimulant, and in doses which were seldom efficacious in reducing the febrile symptoms, but which rarely failed in reducing the vital powers of the patient. I frequently saw the effects of this substance while it was in vogue, and sometimes prescribed it; but I considered it of inferior utility to ipecacuanha and to sulphate of zinc as an emetic in phthisis, their operation being facilitated and increased by a draught of a weak infusion, tepid, of chamomile flowers. Afterward demulcents or emollients, or stomachics, with the addition of a little hydrocyanic acid, if the retching or vomiting be more than we desire, may be prescribed, and subsequently the other internal remedies which the features of the case will suggest.

317. The effect of the emetic early in this stage, and the repetition of it when the functions of digestion are disordered, will generally be beneficial, as shown by the appetite and the state of the evacuations, especially when followed by the medicines just mentioned, or by small doses of the nitro-muriatic acids taken in the tonic infusions already noticed, or in others which the state of the case appears to require. If the bowels become irritable, the tinctura camphoræ comp., or the pilula saponis composita, will correct the disorder; the former being given in the mistura cretæ, or any other suitable vehicle or form of combination, the latter with small doses of ipecacuanha, and of an aromatic powder. If the biliary secretion be deficient, as not infrequently observed in this period, although the bowels are relaxed, PLUMMER'S pill or blue pill may be cautiously given, with soap and extract of taraxacum, instead of the nitro-muriatic acids; or these latter may be prescribed instead of the mercurial, an occasional dose of which should only be taken. In this stage of the disease the bowels are more frequently confined than much relaxed, and the intestinal secretions and excretions are very often more or less disordered. It thus becomes an important object to improve these secretions, and to regulate the function of defæcation. The medicines just named will often aid in attaining this end; but they require to be either conjoined with others, or followed by suitable laxatives or aper-

ients, conjoined with vegetable tonics, stomachics, &c. I have also observed great benefit result from the following, when appropriately administered or modified:

No. 350. R Pulv. Ipecacuanhæ, gr. viij.; Extracti Fel-lis Bovini, ℥ij.; Pilulæ Rhei comp. (vel Pil. Aloes cum Myrrha), ℥ijss.; Extr. Conii (vel Extr. Hyoscyami), ʒss.; Saponis Castil., gr. xij.; Olei Anisi, q. s. Contunde bene et divide massam in pilulas xxxvj. quarum capiat duas horâ somni.

No. 351. R Extr. Glycyrrh., ʒss.; Tinct. Aloes comp. ʒss.; Tinct. Conii, ʒj. (vel Tinct. Hyoscyami, ʒij.); Decocti Aloes comp. ʒvss. Aquæ Carui ad ʒviij. Misce. Fiat mist. ejus capiat cochl. ij. vel iij. ampla horâ somni vel primo mane.

No. 352. R Pilulæ Rhei comp., ℥ijss.; Pilulæ Scillæ comp. et Pilulæ Conii comp., aa., ʒj.; Saponis Castil., gr. x. Contunde bene et massam divide in pilulas xxiv. Sumantur binæ horâ somni.

318. These medicines are most suitable in cases devoid of any inflammatory complication, which, as occurring either in this or in subsequent stages, will be more particularly considered in the sequel. The objection of not being applicable to these and other complications cannot, however, be urged against equal proportions of magnesia and sulphur as an aperient in this stage, especially when rendered more agreeable by the addition of liquorice powder and a little ginger. Where this aperient proves too depressing, or where vital power and vascular action and assimilation are much impaired, a little powdered casearilla may be added to the former, the whole being taken in some water.

319. *b. External medication* is a very important part of the treatment of phthisis; and, as will be seen from the historical sketch given above (§ 242, *et seq.*), it has been considered such from a very early period of medical history. Probably external derivation by means of moxas was as early resorted to in eastern countries for this and other diseases, as by issues and setons among the Greeks and Romans; but there can be no doubt of the benefit to be derived from these and similar means in aid of judicious internal treatment and regimen. As it was in respect of internal, so it has been as regards external means, different kinds and various modes of prescribing them having been advised in successive ages, and those which had fallen into disuse having been revived from time to time, again to be neglected or forgotten. The moxas employed in far eastern countries from time immemorial came into vogue in Europe after the former were visited by voyagers and travellers from the latter; but failed in superseding issues and setons, which have always held their place, and deservedly, in the treatment of this disease, especially with the judicious and experienced. Early in the present century moxas came again into use in some places on the continent of Europe, and pustulation by means of tartarized antimonial ointment, or of croton oil in this country; the latter means having so entirely superseded issues and setons as to have caused the complete disuse of them. I have seen much of these modes of derivation, and have had considerable experience of their effects, both in phthisis and in other diseases. *Moxas* are of more or less use according to the amount of discharge which may be procured subsequently to their incandescence; but their operation is uncertain. Both the tartarized antimonial ointment and the croton-oil liniment produce external irritation, but little discharge, their influence on the disease being seldom beneficial,

while they distress the patient and even augment the constitutional disturbance in some cases.

320. *Issues*, made sufficiently large, have proved most beneficial in my practice. I have always prescribed them when I have seen the patient in the first, or even in the second stage, and several persons are now alive who had recourse to them from twenty to thirty years ago, as I advised them. I have generally recommended them to be made near the margins of the ribs, when the patient is not much emaciated; or in any other situation which may be preferred. The chief objection to them is the preliminary measure of destroying the integuments for the lodgment of the peas. Where *setons* appear preferable, as respects the state of the patient, or the situation in which they may be inserted, so as least to incommodate him, care should be taken, in respect of them as well as of issues, that they should be sufficiently large to be effective, and that a free purulent discharge be uniformly procured from them. When both issues and setons are objected to, especially the formation of an issue in the usual way, then the inner bark of the mezereon, previously moistened, may be placed on a part of the surface of the extent of a crown-piece, and confined there by means of a larger piece of adhesive plaster spread on paper or leather, the bark being renewed from time to time. This latter plan, however, is not preferable to a blistered place of this extent kept open and discharging by the usual means; but neither the one nor the other is so effective as an issue or a seton, the benefit being derived chiefly from a uniformly copious discharge. When this is procured, the internal treatment and regimen of the patient should be more restorative and generous than in other circumstances of the disease; tonics, chalybeates, animal food, restorative beverages, &c., being allowed, according to the peculiarities of the case, especially as respects the vital and vascular conditions.

321. I have, since 1819, never neglected to prescribe an embrocation to the chest, in phthisis and in some other diseases, which acts less as an external irritant and derivative than as a source from which a salutary agent is inhaled into the lungs in so mild a form as neither to irritate nor to stimulate, while it is slightly absorbed. This embrocation I have employed in many internal diseases, in various forms or modifications, as a liniment, or as an embrocation or epithem—sprinkled on folds of flannel, or on spongio-piline, and covered over by a napkin, or otherwise—and varied as respects the constituents, the principal one being always present.

No. 353. R Linimenti Terebinthinæ, Linimenti Camphoræ compositi, ʒiij, ʒjss.; Olei Olive, ʒss. ad ʒvj.; Olei Cajuputi, ʒj. ad ʒjss. Misce et sit embrocatio.

No. 354. R Linimenti Terebinthinæ, Linim. Saponis cum Opio, ʒiij, ʒj.; Linim. Camphoræ comp., ʒjss.; Olei Cajuputi, ʒjss. Misce.

322. When it is desired that external irritation should follow the first of these, the olive oil may be omitted. Either of these should be renewed every night, the vessel being previously shaken, and applied, by the means already mentioned, to a sufficiently large surface, either of the front, or of the back of the chest, or of the side, where pain or uneasiness is most felt. It should be kept applied all night, or the following day, and even be renewed again in the morning, the quantity sprinkled over the surface of the flannel or spongio-piline being sufficient to moisten, or more complete-

ly to wet these substances, according to the effect we wish it to produce, whether by inhalation of the fumes proceeding from it, or by the external derivation it may occasion, in addition to the former mode of action.

323. Blisters, mustard poultices, the cauteries, urtication, and dry-cupping have severally been resorted to as derivatives in this stage. Blisters are often of much service, especially when applied after local depletions; and when a discharge has been procured from them for some time. The others, excepting the cauteries, are seldom productive of much or permanent benefit. The tartarized antimonial ointment and liniments with croton oil have deservedly fallen into disuse. The actual and potential cauteries were not infrequently employed in former times for this disease, a discharge from either having always been promoted. They are now never resorted to in phthisis.

324. c. In this, as well as in more advanced stages of the disease, the *inhalation* of medicated vapours, and of certain fumes, effluvia, and odours, has been recommended and been adopted. I have, however, very rarely observed much benefit derived from it, especially as commonly employed by means of an inhaling apparatus. The substances, also, generally prescribed for inhalation have been used in so concentrated a form, or are so acrid or stimulating, as often to increase the existing irritation in the bronchi, or the morbid action in the substance of the lungs, and in the seats of vomica or of cavities. It is also very questionable whether or no the inhalation of vapours—whether watery, emollient, or anodyne, or narcotic, or possessed of all these properties—is actually beneficial in phthisis, more especially at an early period of the malady. The inhalation of these may be useful as palliatives at an advanced stage, especially when an irritable cough, a sense of constriction in the chest, difficult expectoration, &c., are much complained of; but, in other circumstances and stages of the disease, they only tend to obstruct or impair the functions of the lungs, by interrupting the progressive metamorphosis and oxygenation of the globules of the blood, and by favouring congestion or a partial collapse of the organ. The modes of inhalation, or of having recourse to the respiration of the effluvia of substances which are calculated to prove beneficial in this disease, will be considered in the sequel.\*

325. *C. Treatment of the second stage of the common form of Phthisis.*—At the commencement of this period, or when the symptoms, especially the appearances of the expectoration, and the character of the febrile action, indicate the recent supervention of this stage on the first, then it

\* [We unhesitatingly concur in the truth of these remarks, as will doubtless every practical physician who has had much experience in regard to inhalation in this disease. That it may palliate the cough, when harassing and of an irritative character, when proper substances are used, is a matter of common observation; but we cannot admit that it exerts any decided curative power. Forceful inspiration, which expands the air-vesicles, is far more efficient than the local contact of aerial or vapoury medical agents; for a more perfect oxygenation of the blood aids materially the nutritive function, primary and secondary assimilation. It is possible that certain substances, such as chlorine and iodine, which act as stimulating and tonic alteratives, when introduced into the circulation, may exert the same curative influence as when taken into the stomach. But these are few in number, and it is very possible that the local irritant effects exerted on the lungs may overbalance any good effects which they otherwise might produce. We reserve further remarks on this and other allied topics to the APPENDIX.—Ed.]

will become a question how far the means which have been or still are in use may be continued, and in what they may be modified or changed, or what additions may be made to them. In this the physician will be guided by the peculiarities of each case; but in the circumstances of most the same principles and means as have been discussed should be continued, modified so as to meet prominent symptoms, and commencing or fully developed complications, or intercurrent affections. The softening of the tubercles in this stage is generally attended by an increase of cough and expectoration, of the hectic symptoms, and of the morning perspirations, with occasional attacks of diarrhoea or disorder of the bowels. One or more of these usually become more prominent as the disease advances; or other phenomena are superadded, requiring the treatment to be directed more especially to them.

326. *a.* The cough generally suggests palliatives, in connexion with the other means which the state of the patient demands. Thus hydrocyanic acid, or henbane,\* or hemlock, or the compound tincture of camphor, may be added to mixtures containing the liquor ammoniæ acetatis, and any demulcent which may appear most appropriate to the nervous and vascular conditions of the case; or they may be conjoined with bitter or tonic infusions or decoctions, when the states of the pulse, of the fever, and of the vital powers require them: these latter are often rendered more beneficial by the addition of the solution of the acetate of ammonia, and of the sweet spirits of nitre. Where there is much pallor of the surface, the pulse being either weak or but little accelerated, any of the anodynes above mentioned may be added to the *mistura ferri composita*, and the effects upon the cough and upon the hectic and other symptoms carefully observed.

327. *b.* The perspirations during the night or early part of the morning are always productive of great exhaustion, and are the most difficult to restrain or prevent. They have been very differently treated by both ancient and modern physicians, but most frequently by mineral acids, and by various refrigerants, astringents, and tonics, as shown in the historical sketch given above (§ 241, *et seq.*). Either of these may be prescribed in combinations suited to the case, with emollients, stomachics, or tonics, and may be made the vehicle, on the surface of which the recent cod-liver oil may be taken shortly after a meal, twice or thrice daily, and in sufficient quantity; this being the substance most deserving of reliance for moderating this distressing symptom. Some of the medicines advised with this object have often disordered the bowels, or induced an attack of diarrhoea, and even augmented the suffering of the patient, without effectively diminishing the perspirations and their consequent exhaustion; but these results rarely follow from the use of

this oil. The *mistura ferri composita* is sometimes of service in allaying the severity of the hectic and the excessive perspirations, especially when there is no inflammatory complication present, and when it neither produces headache nor renders the cough harder or more severe. Dr. Watson has found the *tinetura ferri muriatis* successful in allaying the perspirations after other means had failed.\* The dose he prescribes of this medicine is twenty minims thrice daily. I have likewise given this preparation with advantage in the infusion of calumba, with an additional quantity of the acid, and have sometimes made this combination the vehicle on the surface of which the cod-liver oil was taken.

328. *c.* When diarrhoea occurs it is often induced by some purgative medicine, or by errors in diet, or by means employed to moderate the perspirations. The cause of it should be ascertained, and the medicines to restrain it be suggested or selected accordingly. It is, however, frequently independent of either of these causes, and the result of indigestion—of the acidity and the accumulation of sordes in the *prima via* consequent upon the imperfect performance of the functions of primary assimilation. In either of these circumstances antacids and absorbents, conjoined with muelages, anodynes, or narcotics, or with mild tonics, will prove of service; as the cretaceous mixture with the compound tincture of camphor, or the tincture of hop, &c., and with the tincture of catechu, or with other vegetable astringents, if they be required. But the bowels should not be confined by these or other medicines; and when there is any risk of such an occurrence magnesia may be given with sulphur or rhubarb, or with casearilla; or the compound decoction of aloes may be prescribed with the tincture or with other suitable medicines.—[Opium is well suited to such cases, and may be used freely with the best effects.]

329. *d.* In this stage of the disease *emetics* and *bleeding* are seldom beneficial, unless the states of the digestive and respiratory functions require a recourse to the former, and the occurrence of pain or the appearance of an inflammatory or congestive complication demand the latter. Ipecacuanha is in most instances the best emetic, and local bleeding the most beneficial, especially when the embrocation prescribed above (§ 321) is afterward applied and duly persisted in. Although it may be necessary to have recourse to these means, others of a restorative or even tonic kind—both medicinal and regimenal—may be equally required; often, however, in different cases, but not infrequently in the same case, and sometimes even soon after the more antiphlogistic measures have been employed. Generally, when local depletions are required, febrifuge medicines, chiefly such as the solution of the acetate of ammonia,

\* [Great caution is necessary in regard to the use of hydrocyanic acid, henbane, or any other powerful sedative in tubercular disease, inasmuch as the vital powers, already prostrated, may be still farther reduced by the influence of the remedies. When there is "great pallor of the surface with weak pulse," we have found the night sweats augmented by the use of the above-named drugs, as well as the *veratrum viride*, and the general prostration aggravated, under which circumstances the disease invariably makes more rapid progress. We have, however, used of late, with apparent advantage, TILDEN'S "*Fluid Extract of Hyoscyamus*," with paregoric, which serves to allay the pulmonary irritation without causing any increase of debility.]

\* [The *oxide of zinc* will be found one of the most efficacious remedies for the night sweats of phthisis. It may be made into a pill with *extract of hyoscyamus*, two grs. of each to a pill, of which one, and in some cases two, may be taken at bed-time. Dr. BARLOW recommends one gr. *sulph. zinc* and four grs. *ext. of hyoscyamus* to be taken in one pill at bedtime, and generally finds it successful. As the *oxide of zinc* is insoluble, Professor WOOD advises the use of the *sulphate*; but though the former, like calomel and many other mineral substances, be insoluble in water, they find their appropriate solvent in the stomach or intestinal canal; so that, in fact, the *oxide* is just as efficient as the *sulphate*, and less irritating to the mucous membrane. We have found a combination of *sulphate of quinine* and *morphia* very useful for the night sweats of phthisis.]

camphor mixture, &c., are the most appropriate; but they may be afterward conjoined with others of a more tonic nature, such as the infusion of hop or the infusion or decoction of cinchona, and to these anodynes may be added, the selection of which should depend upon the features of the case. Hydrocyanic acid, monkshood, hemlock, henbane, meadow-saffron, and digitalis, have been individually employed in combination with these or other medicines; but they require caution in their use, and careful observation of their effects. Monkshood, or *aconite*, is most appropriate in the more inflammatory tendencies of this and the preceding stage, but it especially demands a most cautious observation of its effects; a remark not less applicable to colchicum and digitalis, which are suited to the same states of the disease as those for which *aconite* may be given; these being useful chiefly as antiphlogistic means, either in aid of vascular depletion, or when the condition of the blood and of vital power contra-indicate a recourse to depletion; although the local morbid action requires to be restrained or even lowered.

330. *c.* The remarks offered above respecting *issues*, *setons*, and other derivatives (§ 319–323), apply to this as well as to the first stage. Instances are rare in which either the one or the other should not be resorted to. The great difficulty often is, owing to the emaciation of the patient, in which situation they may be placed, so as to produce the least amount of discomfort. When emaciation is not very remarkable, then the margins of the ribs may be selected; but in different circumstances an issue of good size may be formed over the pectoral muscle, or between the shoulder-blades. When this stage in females is characterized by suppression or marked diminution of the catamenia, the issue may be made near the groin, in the anterior aspect of the thigh. When setons are preferred, the arm, near the axilla, may be selected. If neither of these nor moxas be adopted, *blisters*, kept open as long as possible, and renewed from time to time, are generally necessary. The *embrocations* advised above (§ 321) ought not to be overlooked, inasmuch as, in the more urgent cases, they may be applied while the foregoing means are also in operation, and as they are sources both of derivation and of inhalation. When the above produce a sufficient discharge, then GRIFFITH'S myrrh mixture, or other chalybeates or tonics, may be prescribed, with anodynes, narcotics, &c.; and their effects upon the cough, the pulse, and the hectic should be carefully observed. If these symptoms become aggravated by them, they ought to be relinquished, and the salines, especially the solution of acetate of ammonia, or of eitate of potash, with hydrocyanic acid, conium, &c., as noticed above (§ 329), may be substituted. If these effects do not result, then the more generous regimen recommended for the first stage (§ 314, *et seq.*) is equally, if not even more, required for this.

331. *f.* *Inhalation* of dilute medicated vapours and fumes may be tried in this stage, as well as in the first. The opinion I have formed of them, and stated with reference to that period (§ 324), is not materially different as regards this. Cases may occur in which they will be more serviceable in the second than in the first stage, and still more so in the third than in either of the foregoing; but the amount of benefit, or the want of it, will entirely depend upon the substances selected for this mode of administration, and upon the way

of effecting this intention (*see* § 412). But mild or weak *fumigations* of the patient's apartment are generally much more beneficial than inhalations, which often irritate and increase the local lesions (§ 413).

332. *g.* In females the state of the *catamenia*, as respects both the intervals and the duration and quantity of the discharge, is of the greatest importance, especially in the first and second stages of the malady. Excessive discharge, whether as to frequency of recurrence, the duration of its continuance, or the quantity, not infrequently predisposes to, or more directly occasions, phthisis; and the same disorders of this function, if allowed to proceed, will also aggravate or hasten the progress of this malady, if they occur in either the first or second stages. The rapid or sudden disappearance of this discharge, on the other hand, is even more certainly and rapidly injurious, in whatever stage this may take place. A difficult or scanty catamenial discharge requires attention, although it is not so dangerous as either of the former states, especially the latter. Excessive states of the catamenia should be moderated with caution, and by such means as are not likely to be followed by suppression. The decoction or infusion of cinchona with either of the mineral acids, or the sulphate of quinine in the compound infusion of roses, and tincture of orange-peel may be prescribed, or the sulphate of quinine may be mixed in some water and taken without any addition. If anæmia have been produced by this discharge, the tincture of the sesquichloride of iron may be given, either alone or with the preparations of calumba or quassia. It should not be overlooked that the disorders of the catamenia in the early stages of phthisis are often caused by masturbation; and when this is suspected, and when advice can be prudently given and precautions taken against this vice, it becomes the duty of the physician to act accordingly. In these, as well as in other circumstances of profuse catamenia, ipecacuanha, conjoined with extracts of gentian, catechu, and a narcotic, may be given in such quantity as to occasion some degree of nausea to even retchings.

333. Scanty or difficult menstruation requires means appropriate to the peculiarities of the case; for either of these states may be attended in one patient with an anæmic or chlorotic appearance, and in another with little or no apparent deficiency or poorness of blood. In the former case, the compound mixture of iron, with as much of the compound decoction or the tincture of aloes as will act moderately on the bowels, or prevent constipation, with a little of the extract or tincture of conium, will generally be of service. In other cases, where there is no deficiency of blood, a few leeches may be applied below the groins shortly before the expected period of the catamenia; and the hip-bath and pediluvia, at a sufficiently warm temperature and with the addition of salt or mustard, resorted to.

334. In cases attended by suppression of this discharge, strenuous efforts should be made to restore them. The hip-bath, pediluvia, &c., rendered stimulating by bay salt and mustard, leeches applied around the anus or beneath the groins, the preparations mentioned above (§ 333), walking exercise, or riding on horseback or in a carriage, and the several emmenagogues advised for suppression of the catamenia (*see* MENSTRUATION, § 64–95, *et seq.*), should be prescribed in combi-

nations or forms suited to the state and stage of the pulmonary disease.

335. In this stage various complications appear, either as temporary or intercurrent affections, or as morbid associations, which continue to the termination of the malady. These will be noticed in the sequel; but there is one which is rarely absent, and which renders the treatment difficult, namely, the bronchitic affection. This, in many cases, becomes the prominent disorder, and requires the treatment to be more especially directed to it; the most generally serviceable means being, according to the accompanying fever and the state of the patient, the solution of the acetate of ammonia with the spirit of nitrous ether, dilute hydrocyanic acid and camphor mixture; or in somewhat different states, with carbonate of ammonia, compound tincture of camphor, or henbane or opium. If there be a hæmorrhagic tendency, the acetic acid may be added; and in most cases the terebinthinate embrocation should be applied to the chest.

336. *h.* The diet and regimen in this stage may in a very large proportion, if not in the majority of cases, be altogether the same as I have advised for the prevention and for the treatment of the first stage of the disease (§ 292–308). In many cases a fish diet will agree well in this stage; the white kinds of fish, always boiled, but never fried, a squeeze of lemon, with little butter, but preferably with the liver of fish, being the chief or only sauce. The fish and their livers, which are most beneficially used as articles of diet, are the *Gadus brosmius*, or torsk; the *Gad. morrhua*, or cod; the *Gad. molua*, or ling; the *Gad. æglefinus*, or haddock; the *Gad. merlangus*; the *Gad. callarius*; the *Gad. carbonarius*, or coal-fish; the *skate*, *turbot*, *soles*, &c. The recent livers of all these species of the genus *Gadus*, boiled in such a manner as to preserve their oil, may be used either as sauce to the fish, or may be eat with it, or the oil may be taken after the meal, in the usual medicinal way. They are beneficial both as articles of diet and as medicine. When quite recent they have no fishy or unpleasant flavour, and are easily digested—the more easily the more oil they contain.

337. As to other articles of diet, regimen, change of air, exercise, travelling, voyaging, and choice of residence, the remarks which I have made above (§ 292–308), and in the sequel (§ 420, 421), and in the article CLIMATE (§ 42, *et seq.*), are applicable to this stage, according as the strength of the patient and the prominent symptoms will admit of their adoption, and as the presence or absence of any of the more important complications will suggest.

338. *D.* The treatment of the third stage of the common form of phthisis (§ 38, *et seq.*) is frequently but little different from that already advised. The state of the patient may not, in some instances, be materially different from that characterizing the second stage, although cavities—one or more—have already formed in one or even both lungs. The patient may not be materially worse in respect either of strength or degree of emaciation, or of cough and respiration, especially if the more aggravated symptoms and complications have not as yet been experienced. More commonly, however, he is much worse as regards all these; and colliquative perspirations, attacks of diarrhœa, severe paroxysms of cough and of oppressed breathing, and pains in various

parts of the chest or its vicinity from inflammatory congestion of portions of the lungs or from the extension of the morbid action to the pleura, are more or less experienced, and are generally relieved with greater difficulty than in the preceding stages. The treatment depends chiefly upon the complication, or rather complications, which characterize this stage.

339. *a.* In all cases there is more or less *bronchitis*, chiefly, however, of the bronchi communicating with the softened tubercles and cavities; but there may be in addition *inflammatory* or *sub-inflammatory* action in the surrounding portions of lungs, or even also in parts of the pleura in the vicinity. These may require, or at least suggest, a treatment which neither the strength nor vascular condition of the patient may well bear, especially when carried so far as to subdue the superinduced local mischief. But to leave these complications to their natural courses, when clearly manifested by symptoms, may be more injurious than the effects of judicious means prescribed for their removal; and, as far as my experience enables me to decide, the employment of such means is the safest alternative. For these states of this stage, therefore, local depletions, by leeches or by cupping, are required, according to the condition of the patient and symptoms of the case, the quantity of blood taken at first being small. When the indications for having recourse to this measure are doubtful, dry-cupping, afterward blisters, the terebinthinate embrocations already advised (§ 321), and the febrifuge medicines recommended above, are most appropriate. Of this class of medicines, the solution of acetate of ammonia, in forms and combinations already noticed (§ 315), is the most generally of service.

340. *b.* In this stage, especially in its advanced course, the colliquative perspirations and diarrhœa exhaust the patient, and more or less waste the red globules of the blood. While these symptoms should be restrained, the powers of life and the supply of duly assimilated blood-globules must be supported and promoted. The means which fulfil the one indication often also aid the other. This is more particularly demonstrated by the effects of cod-liver oil, and by medicines which improve the digestive and assimilating processes, and correct, counteract, or remove the contaminating matters which are carried into the circulation from the lesions seated in the lungs, whether softened tubercles or ulcerating cavities, and which thereby affect the cutaneous and mucous surfaces and follicles, so as to give rise to these exhausting and distressing symptoms of the malady. Numerous means, beside those already mentioned, have been proposed for these morbid conditions, especially the acetate of lead with pyroligneous acid and laudanum, the sulphate of zinc with sulphuric acid, the sulphate of copper with opium, the substances containing tannin, gallic acid, &c., and catechu, kino, krameria, hæmotoxylum, nux vomica, &c.; but very few of these, even while they restrain the diarrhœa, diminish the perspirations, or in any other respect alleviate the malady. Indeed, in some cases they aggravate the disease, and only accelerate its progress to a fatal issue by preventing the elimination by those emunctories of the effete, morbid, and contaminating materials conveyed into and circulating in the blood.

341. *c.* Much more rational and efficient indications for the abatement of the colliquative diar-

rheæ and perspirations in phthisis would be the improvement of the digestive and assimilating functions by such means, or combinations of means, as would at the same time, by their partial absorption into the circulation, correct, change, or counteract the contaminating matters which are imbibed from the seat of the disease; whether these matters be purulent or tubercular, or the sanious fluid formed in or on the surface of ulcerating parts, and whether they are actually present in the blood, or are more or less changed in the course of the circulation of the blood. That they actually contaminate more or less this fluid, however small may be the quantity which passes into it, and thereby give rise to the most distressing and dangerous symptoms of phthisis, cannot be doubted, the skin and the bowels being two of the chief channels through which they, and other injurious matters they may form, are eliminated from the circulation; but the selection of the means of fulfilling these indications is much more difficult than devising them, and depends entirely upon the peculiarities of individual cases, as respects especially the progress of the disease and the states of respiration and circulation. The bicarbonate and the nitrate of potass, prescribed in tonic infusions or decoctions, with aromatic or astringent or narcotic tinctures, according to the state of the case; magnesia and sulphur, with the powder of cascarrilla or of cinnamon or ginger and liquorice powder, or with other substances, as the state of the bowels will suggest; the compound iron mixture, or the aromatic mixture of iron (D. P.); the bitter or tonic infusions, with carbonate or citrate of potass or of soda and anodynes; balsams, the purified or inspissated ox-gall, with conium or with the compound soap pill and ipecacuanha, or with the purified extract of aloes, according to circumstances; and camphor, the terebinthines, tar or tar water, conjoined with such of the foregoing medicines as the features of the case require, may severally be employed. In some instances where the colliquative state of the bowels and other symptoms indicated a contaminated state of the blood, and consecutive alteration of the mucous surface and follicles of the bowels, I have prescribed the following pills at night, or night and morning, or with the meals; the bitter vegetable tonics, with alkalies, &c., having been taken in the intervals between meals:

No. 355. R Pilulæ Ferri comp.; Pilulæ Rhei comp.; Extracti Fellis bovini; Picis liquidæ, ʒi. ʒss. Misce et contunde bene, dein divide massam in pilulas xxx.; quarum capiat unam ad tres pro dose.

No. 356. R Extr. Fellis Bovini; Sulphuris præcipit.; Picis liquidæ; Confect. aromat. in pulv., ʒi. ʒss.; Olei anisi, q. s. Contunde bene et divide in pilulas xxxvj. Sumat j. ad iij. pro dose.

No. 357. R Magnesie carbon.; Sulphuris præcipit., ʒi. ʒij.; Confect. aromat. in pulv. ʒss.; Creasoti ʒi. ʒij. ad xij.; Olei anisi, et mucilag. q. s. Misce et fiant secundum artem pilulæ xxxvj. Capiat j. ad iij. bis terve in die.

342. It may be noticed that the above, both mixtures and pills, may be modified, or receive additions, so as to meet the peculiarities of the case. If irritation or pain in the bowels be experienced, small doses of the extract of opium or the soap pill with opium, may be added to either of the foregoing; and if diarrhœa, or tenesmus, or dysenteric symptoms be present, ipecacuanha in full doses may also be conjoined with these.

343. With the other distressing symptoms, to which I have directed notice, there are others for

which relief is required, and although we may be unable to impart it, we should at least attempt it. The dyspnœa, difficulty of breathing, the feelings of suffocation, &c., in this stage, are sometimes distressing. In many instances the terebinthinate embrocations already mentioned (§ 321), applied over the chest or between the shoulders, will afford some relief; and an opiate conjoined with either of the pills just prescribed, or with expectorants and antispasmodics, or the compound galbanum pill, or with stimulants and other means indicated by the state of the case, as already mentioned, will often be of service. When the dyspnœa is urgent or distressing, an emetic will be found to afford most relief. The aphthæ which, towards the close of this stage, often appear in the mouth, tongue, and throat, farther increase the distress of the patient, and require the treatment advised for this condition of the mouth and throat in the articles THROAT (§ 40, *et seq.*) and THRUSH (§ 11, *et seq.*).

344. *d. Delirium* rarely occurs in this form of phthisis until shortly before dissolution, unless in females, when this stage of the malady is accelerated by, or occurs in the puerperal state, or in cases where the nature of the medicines or the idiosyncrasy of the patient has given rise to this symptom. Most of the narcotics and anodynes, especially henbane, conium, aconite, opium, morphia, digitalis, &c., will have the effect of inducing delirium in the advanced progress of this stage, especially in nervous and exhausted states of the patient, and when either of these substances are given in too large doses, or continued too long; or when substances which are calculated to prevent or to correct their injurious effects have not been conjoined with them. The delirium, in most instances, is slight; but it is sometimes more severe or acute, and is attended with restlessness and sleeplessness, or it approaches the character of delirium tremens. For these modifications of mental disorder, lowering means only hasten a fatal issue. If they have been occasioned by either of the medicines just mentioned, they will frequently disappear after the cause has been removed, especially if judicious means be prescribed; but under every circumstance the state of vascular action, especially as respects the brain and membranes, should be observed. If it be increased in these, cold-sponging the head, mustard pediluvia, &c., are required; and even when such increase is present, it will be more readily relieved by restoratives, prescribed in small and moderate doses, and their effects watched, than by opposite means. The medicines from which most relief may be expected in the delirium occurring in this period, are camphor, ammonia, the solution of the acetate of ammonia, the carbonate of ammonia, the compound spirit of ether, the spirit of nitric ether, the hydrochloric ether, the preparations of serpentaria, of arnica, and of sumbul. These may be prescribed individually, or in combinations of two or more, or with the alkaline, saline, and restorative medicines I have mentioned as being useful when the blood is contaminated, the delirium often arising from that condition, as well as from exhausted organic, nervous, or vital influence.

345. *v. TREATMENT OF THE LATENT FORM OF PHTHISIS.*—This variety of the disease (§ 77, *et seq.*) generally eludes the notice of the friends and the fears of the patient until it has advanced

to a state hardly admitting of hope. If, however, the symptoms characterizing it should alarm either friends or patient, if depression of spirits, impaired digestion and assimilation, or other indication of disorder lead to the procuring of medical advice, and the detection of the malady in its silent and stealthy course, although no prominent or unmistakable sign be present, the treatment which will be found most beneficial is that which has been already advised for the *prevention* and for the *threatened appearance* of the malady (§ 292-298). It is obvious, however, that the best-devised means will have no beneficial effect if the causes which injured the constitution still continue to act. The physician should endeavour to ascertain what these are; and if they be such as may be removed, the necessity of making the attempt should be insisted upon, and the patient be made acquainted with the consequences of the neglect of this advice, especially when the removal of these causes depends upon himself. In most of the cases of this variety the causes are usually depressing and exhausting; and in many, as soon as the nature of the malady is suspected, the digestive and assimilating functions require restoratives, mild tonics, change of air, moderate exercise in the open air, travelling, and pleasurable occupation of the mind; the regimenal and medical treatment I have advised above (§ 299-324) for the first stage of the usual form of the disease being also necessary. In this latent or silent course of phthisis vascular depletions are not well sustained; and if they be at all attempted, they should be small, and their effects watched. In the great majority of cases of this form, and especially when depressing or exhausting causes have occasioned the malady, medicines of a decidedly restorative or tonic kind, attention to the digestive functions, cod-liver oil, and the other means recommended at the place referred to, should be adopted. These may arrest the disease; but if it should advance nevertheless, and become unmistakingly developed, the treatment must necessarily be the same as I have advised for the more common form of the malady, modified as above, according to the manifestations of the advanced stages.

346. vi. PRIMARY ACUTE or RAPID PHTHISIS. —A. The symptoms of the *first variety* of this form (§ 82-84) have been described by me as intermediate between those of congestive bronchitis on the one hand, and of congestive or nervous pneumonia on the other (§ 83), both lungs being more or less affected. The cases which I have observed have been consecutive of measles in a serofulous diathesis, or of delayed, suppressed, or excessive catamenia. In these bleeding seemed injurious, or was of no avail. Emetics, the solution of the acetate of ammonia, with ether or ammonia, small doses of camphor, the terebinthinate embrocation applied over the chest or between the shoulders, and blisters, were the means which appeared to be of most service. Cod-liver oil was either not retained, or was nauseated and not taken, or failed of producing any benefit. The infusion or decoction of cinchona, with nitrate of potash and bicarbonates of the alkalis, or with the solution of acetate of ammonia and various ethereal preparations, and small doses of camphor with aconite, &c., were also prescribed in different cases, or in the same cases at different periods of the disease, but with no marked advantage.

347. B. The *second variety*, or more strictly febrile form of acute phthisis described above (§ 85, 86), is often mistaken for low nervous or typhoid fever, which it closely resembles, especially in its advanced progress. In the few cases which have fallen under my observation I prescribed the remedies I have just mentioned (§ 346); and of these, the last-mentioned, or those consisting of the preparations of cinchona with the substances stated to have been conjoined with them, the chlorate of potash, camphor, the terebinthinate embrocations, &c., appeared to be of service only in prolonging the life of the patient for a few days. The nature of these cases precludes any hope of farther advantage than this from any treatment whatever.

348. vii. CONSECUTIVELY ACUTE PHTHISIS (§ 87) is merely the supervention of either of the acute varieties of the disease described above (§ 81-86) upon the latent form (§ 77-80), of the development of this latter form owing to an attack of hæmoptysis in its course, or to some determining or aggravating cause or occurrence. Although an attack of hæmoptysis often relieves the pulmonary symptoms when they have been unequivocally manifested previously, at least for a time; yet it is sometimes followed by an acute state of the disease, most frequently by the more common form, when it occurs in the course of the latent variety. In the consecutive manifestation of acute symptoms the treatment should depend upon the character of these symptoms and upon the associations they present. If hæmoptysis take place, the treatment I have advised for it (§ 353-5) may be adopted as far as it may be appropriate to the peculiarities of the case. If the local symptoms and signs indicate congestion or inflammatory action in one or both lungs, local vascular depletions, or even a repetition of them, emetic, antiphlogistic, and saline medicines, especially the solution of the acetate of ammonia, terebinthinate embrocations, blisters, and other means already noticed, will be of service; and if the disease assume the acute or febrile states, the medicines noticed above (§ 346, 347) may be prescribed, although with little or no hope of benefit from them. In some instances the malady assumes a less acute or febrile form, the treatment having temporarily mitigated the severity of the symptoms. This is probably owing to the congestive and inflammatory states of the bronchi and substance of the lungs, which had supervened upon an extensive but latent formation of tubercles in both lungs, having been partially subdued by the means employed. In these cases the development of the tubercles by the morbid action in the bronchi and substance of the lungs afterward prevents this action in these parts to subside; and thus both these morbid conditions act and react on each other, so as to occasion an acute state of disease. The extension of these lesions in a more or less marked degree through both lungs generally terminate fatally before large cavities, or even any cavities, are formed.\*

\* Of 750 cases of acute pneumonia treated in the great hospital of Vienna from 1847 to 1850, pulmonary abscess was observed in but a single instance, and with regard to the physical signs of excavations thus formed, SKODA remarks as follows: "I have frequently examined patients suffering from pneumonia, in whose lungs newly-formed abscesses were found after death; but I have never, in any single instance, recognised the presence of abscess by the aid of auscultation or percussion. In every case, the abscess, though communicating with the bronchial tubes, was filled with pus or sanies."—SKODA

whereas, in the common form of the disease, the greatest part of the lungs remains free from change, although other portions are ulcerated, excavated, or otherwise disorganized. In these circumstances the principles of treatment already developed should be adapted to the peculiarities of individual cases.

349. viii. PROTRACTED PHTHISIS (§ 89-91), especially when early recognised or manifested, and judiciously treated, furnishes many chances either of recovery or of prolonged existence. For this variety, particularly when the pulse and respiration are not much disturbed, the several Hygienic means advised for the *prevention* of the disease and for the treatment of the first stage (§ 292-323) are generally of great service, more especially change of climate, voyaging, exercise and agreeable occupations in the open air, and in a dry and temperate situation, attention to the digestive and assimilating functions, aided by digestible and nutritious food; by sulphur, balsams, a farinaceous and milk diet, &c.; by tonics, stomachics, and chalybeates when the disease appears to have proceeded from depressing or exhausting causes; and by emetics and other antiphlogistic means, or by small bleedings, issues, setons, terebinthinate embrocations, blisters, &c., according as vascular excitement or congestive or inflammatory complications may occur. In the simpler states of this form, when the pulse is weak or slow, and no congestive or inflammatory complication is present, and especially if the blood be deficient or thin, the *mistura ferri composita*, or the *tinctura ferri muriatis*, will be given with benefit; and with either of these other medicines may be conjoined, especially cod-liver oil, anodynes, &c.

350. ix. PHTHISIS IN INFANTS AND CHILDREN (§ 92-95) requires more particularly the Hygienic measures I have recommended under the head SCROFULA AND TUBERCLES (§ 148-153); and in the sections above on the *prevention* and *early treatment* of the usual form of phthisis (§ 292-308). Asses' milk, a milk and farinaceous diet, moderate exercise in the open air, change of climate, strict attention to the promotion of the digestive and assimilating functions by means of diet, regimen, and suitable medicine, the cod-liver oil in as large quantity as the stomach will bear, and taken in the modes hereafter to be noticed, are the chief means in which confidence can be placed, although others should be added whiel the circumstances of particular cases will suggest. When the disease advances to the second or third stage in children, then the treatment advised above for these stages, in the usual form of the disease, will, with due reference to the ages and states of the patients, be equally appropriate for them.

351. x. PHTHISIS IN THE DARK RACES (§ 96, and *note*)—The forms and states of the disease may reasonably be considered as varying with race and climate (§ 200-222), and also with the habitual food and clothing, or amount of clothing, of these races (§ 219-222, 420, 1. and CLIMATE, § 42, *et seq.*) From what I have seen or gathered from writers respecting the disease in these races, I conclude that for them a tonic and restorative treatment, with attention to the digestive organs and to the functions of the skin, is espe-

cially and generally required. In other respects the means of cure advised above for the several forms of the disease in the white races are also suited to these forms when they appear in the dark races. In these latter the causes are commonly depressing and exhausting. Confinement to close situations, where the air is rendered impure by frequent respiration or by numbers, removal to colder and more humid climates than those from which they have been taken, venereal excesses, and insufficient food, are the most frequent causes of phthisis in these races, and hæmoptysis is a common occurrence at the accession or early stage of the disease. For these the more astringent tonics, the preparations of cinchona or of cascarilla, conjoined with laxatives or aperients, or with diaphoretics, according to the states of the bowels and skin; ipecacuanha combined with the balsams and restoratives, chalybeates with stomachics, and terebinthinate embrocations externally, are most frequently indicated. If febrile action be present, the warm and restorative febrifuges and diaphoretics are required; especially the solution of acetate of ammonia, the carbonate of ammonia, camphor, and the infusion or decoction of cinchona. If the bowels become disordered, ipecacuanha in large doses, with opiates, the bitter extracts, and such of the medicines already mentioned as the circumstances of the case will suggest, will be found most appropriate. Dr. ARCHIBALD SMITH states that the several dark races, and the crosses between these races, on the coast of Peru especially, when attacked by the hæmoptysie form of phthisis, were most benefited by a residence for several months in the mountains at an elevation of 5000 to 10,000 feet above the level of the sea.

352. xi. TREATMENT OF COMPLICATED PHTHISIS.—The *complications* which severally appear from the accession to the close of this disease require a few remarks. These complications are not confined to any one form or stage of the malady, but occur in all; although more frequently perhaps in some cases than in others, owing to the constitution and predisposition of the patient, to the exciting and determining causes, and to the exposures and other influences in operation during the progress of the malady. Some of these complications may appear in the character rather of prominent or more urgent symptoms than of actual superinduced or intercurrent affections; but as phthisis may, and actually often does, run its whole course without the appearance of any of them, or of one only in some cases, and of another in others, while two or more may occur even in the same case, although not at the same time, they may be more correctly considered as contingent symptomatic affections, complicating, and often rendering the tubercular or original malady more severe and more rapidly fatal. With a few exceptions, these affections have already been considered with reference to treatment when discussing the successive stages.

353. A. *Hæmoptysis* is a frequent occurrence in phthisis. The treatment of it should depend upon the state of the pulse, the age and habit of body of the patient, the stage of the disease, and the amount of blood lost. I have, however, so fully treated of hæmoptysis under the head HÆMORRHAGE FROM THE RESPIRATORY ORGANS (§ 123-141), that it is quite unnecessary to entertain this subject farther than to remark that hæmoptysis is generally the result, at the accession

or at an early stage of phthisis, of capillary congestion arising from the obstruction or irritation caused by tubercular deposits, and at an advanced stage either of the same cause or of exudation from an ulcerated cavity, or of discharge from an eroded vessel or vessels. The older writers, observing the relief following a free discharge of blood at an early stage of the disease, advised that the hæmorrhage should be allowed to proceed for some time. But to do this would often greatly alarm the patient, and be running the risk of the blood passing into and obstructing or irritating many of the bronchi which had remained free from disorder. It is, therefore, safer to arrest the hæmorrhage by suitable means, such as those which I have detailed under the article HÆMORRHAGE (§ 123–141), or by general or local bleeding, or by the internal exhibition of the spirits of turpentine in doses of twenty or thirty drops every half hour or hour, and by the turpentine embrocation or epithem applied over the chest. There are numerous other means which may be employed, and which are mentioned in the article just referred to; but these are most generally of service. The bleeding should be rather repeated than large, and be regulated by the circumstances already stated. Large doses of ipecacuanha, or one or two grains given every quarter or half hour, are also of great service; but if the bowels be confined, half an ounce each of spirits of turpentine and castor-oil may be taken in a suitable vehicle, and the same substances in larger doses administered in gruel as an enema. Dr. CHEYNE advises, especially in cases of hæmoptysis with inflammatory symptoms, a quarter, or even an eighth of a grain of tartarized antimony with five to ten grains of nitre every hour. The chief advantage from ipecacuanha and from antimony is produced by the nausea they occasion. Much, also, of the benefit experienced from sea voyages, especially in this form or complication of phthisis, is produced by the nausea thereby occasioned.\*

354. When called to these and other forms of hæmorrhage I have often found the practitioner assiduously applying cold or ice to the chest. The instantaneous shock or impression of cold sometimes does good; but if this effect does not immediately follow, to persist in these applications, especially in hæmoptysis, always does mischief, by increasing or perpetuating congestion of, and vascular determination to, the lungs.

355. When hæmoptysis has not sufficiently relieved the congestion or the inflammatory symptoms attending it, then bleeding, general or local, should be repeated, according to the effect or to the circumstances at the time or subsequently. When, on the other hand, the quantity of the discharge, the existing symptoms, the stage of the disease, and state of the patient, require an immediate arrest of hæmoptysis, without having recourse to vascular depletion, then the other means advised are the most efficient, the spirit of turpen-

tine or ipecacuanha acting more promptly than the acetate of lead or other astringents. The secale cornutum I have also found to act very promptly in hæmoptysis, five grains of it being given every five, ten, fifteen, or twenty minutes, until it produces the effect, or causes vomiting or much nausea. The repetition of small bleedings, or of other means subsequently, should depend upon the state of the pulse, the existence of *pain* in any part, or of dyspnœa and the state and stage of the disease; but in most cases the terebinthinate embrocations already advised should be continued to those regions of the chest where most uneasiness is felt.

356. *B. Inflammation of portions of the lungs* or of the *bronchi*, or of the *trachea* or *larynx*, followed by more or less of the consequences of these, as stated above (§ 109–112), often complicates phthisis, and requires means of an antiphlogistic kind in some respects the same as those just advised. It should, however, be recollected that the inflammatory action affecting one or more of these parts, owing to its asthenic or congestive character, to impaired constitutional power, to previous disease, and to the associated morbid conditions, admits not of the same treatment as that which is found most beneficial in idiopathic or some other states of this action. Vascular depletions, generally local, as in hæmoptysis and pleuritic attacks, are required, and sometimes should be repeated. When the state of the case admits of venæsection, to however small an extent, this should be preferred to the application of leeches, to which also cupping ought to be preferred.

357. *a. Pain* in the chest, independently of hæmoptysis, is often relieved by small bleedings, by cupping or leeches, by blisters, and by the continued application of the terebinthinate embrocation. The usual cause of this pain—its connexion with *partial pleuritis* (§ 112)—should not be overlooked; and the advantage generally following a recourse to mercurial and antimonial preparations in combination, and sometimes also to anodynes, demulcents, &c., in the intervals between the exhibition of the former, ought to be kept in view.

358. *b. Cough* is often a most distressing symptom, especially in the advanced stages of phthisis, and more particularly when it is associated with *dyspnœa*. In the less urgent states of cough, compound tincture of camphor, or hydrocyanic acid, will often give relief. The preparations of anise seed have long been highly esteemed for their effects in ameliorating the cough and even the dyspnœa. To the preparations in common use Dr. WATSON states that Dr. PROUT preferred an infusion of three drachms or half an ounce of the bruised seeds of anise seed in half a pint of distilled water, at a temperature not exceeding 120°, allowing it to stand until it is cold. This may be made an excellent vehicle for the compound tincture of camphor, hydrocyanic acid, or conium, &c. But the severer attacks of cough, in the advanced stages, require more energetic means, especially the preparations of opium or of morphia. These, however, often are followed by unpleasant symptoms, particularly morphia, if they be not conjoined with aromatics and gentle stimulants—with small doses of camphor, of spirits, or oil of caraway, or of lavender, or of anise seed, &c. Opium may be given in the form of the confectio opii, or conjoined with a little of the confectio aromatica;

\* We have rarely known the *Gallic acid* fail in checking hæmoptysis. Dr. JAMES FOUNTAIN strongly recommends an infusion of the common *Witch Hazel* (*Iamæmelis Virginica*). As the flowers of this singular shrub appear after it has shed its leaves, in autumn, and the fruit is not perfected till the following season, all manner of magical properties have been ascribed to it. It possesses *astringent* properties, and perhaps slightly *anodyne*. An empirical preparation is kept in the shops, prepared from this shrub, which goes under the name of "Coryle Extract," the proprietor mistaking it for the "*Corylus Americæ*" or *Hazel-nut*.]

or the pilula galbani composita, or the pilula saponis composita, or the pilula styracis composita may be prescribed with either of the foregoing. I have frequently preferred the following solution of the acetate of morphia, conjoined with aromatics, in order to counteract the depressing effects often produced by it.

No. 353. R Morphiæ acetatis, gr. vj.; Liq. Ammonia acetatis, ʒj.; Acidi aceticæ diluti, ʒij.; Spirit. Anisi, ʒss.; Spirit. Carui et Spirit. Lavand. Comp., aa ʒijj.; Mist. Camphoræ (vel Syrupi Tolutani) ad ʒijj. misce. Fiat mist. cujus capiat ʒj. pro dose, vel ʒj. hora decubitus, et ʒj. primo mane, in aquæ hordei cyatho vinario.

359. *C. Laryngeal and tracheal affections* are often the most distressing of those which occur in the course of phthisis (§ 109, 110), and in some of the usual or more protracted forms of the disease present more or less of the characters noticed above (§ 109, 110), or of the sub-acute or chronic states described in the article on Diseases of the LARYNX AND TRACHEA (§ 105, *et seq.*). Since this article was written, the diseases of these parts have been ably investigated by Dr. HORACE GREEN. He contends that inflammatory affections of the larynx, trachea, and throat are seated in the mucous follicles. It is, however, chiefly in the sub-acute and chronic affections of these parts that the follicles are either primarily or consecutively implicated, and especially when these affections are complications of phthisis, and are produced either by the protracted irritation of the trachea, larynx, epiglottis, and even of the pharynx and fauces, by cough, and by morbid secretions passing through them, or by the existence of tuberculous matter in their follicles or muciparous glands. At first these sources of irritation and contamination enlarge these follicles, increase their discharge, thicken and somewhat soften the mucous and sub-mucous tissues, and ultimately occasion an ulceration of the mucous follicles, and an atrophy, with increased softening, of the mucous and sub-mucous membranes. That the affection of the muciparous glands, in the advanced course of phthisis, is occasioned not only by the morbid secretions passing over them, but also by the deposit of tuberculous matter in them, is extremely probable. Dr. H. GREEN insists upon this latter change, although it is denied by several eminent pathologists. In either case, the treatment cannot materially differ. Dr. H. G. found this complication of phthisis most frequent between the ages of 25 and 38 years. He also often observed this affection of the throat and larynx after influenza, eruptive fevers, and more particularly in persons habitually using tobacco. Dr. GELLERSTEDT considers the ulcerations so commonly found in the larynx, in phthisis, to be of tubercular origin; while those of the trachea he regards, with LOUIS, as of an aphthous nature, arising from the constant irritation of the cough and expectoration.

360 The treatment of this complication of phthisis has been by inhalation, insufflation, lotions, and the application of the solid nitrate of silver to the tonsils, uvula, and pharynx. Dr. LAYCOCK remarks, in an able article in the *British and Foreign Medical Review* (vol. xxiv., p. 497), that the application of the nitrate of silver to the cavity of the larynx is not, however, to be classed among these ordinary methods; and the practice of it by Dr. GREEN seems to have been received with so much incredulity in the United States, that he has thought it necessary to multiply evi-

dence as to the fact that he has introduced a strong solution of nitrate of silver within that cavity. "TROUSSEAU and BELLOC are supposed, by Dr. GREEN, to have been the first to prescribe and employ topical medication in chronic laryngeal disease. They found a solution of the nitrate of silver, in the proportion of two drachms, or sometimes four drachms, to an ounce of distilled water, to be the most efficacious and harmless application. Two methods were adopted by them: the one was to saturate a small sponge attached to a bent rod of whalebone, and to manipulate so that the solution be expressed into the larynx: the other was to use a small silver syringe, with a tube suitably adapted for effecting the same object. Dr. GREEN, however, several years before the appearance of Messrs. TROUSSEAU and BELLOC's book, had instituted experiments, and come to a similar conclusion." Dr. LAYCOCK farther remarks that, without wishing to disparage the labours of our Gallic or American brethren, Sir CHARLES BELL successfully adopted the method of treatment so fully illustrated by Dr. GREEN; and Dr. L. refers to cases published by Sir C. BELL (*Surgical Observations, &c.*, Lond., 1816, p. 34), for which this practice was employed. Dr. WATSON states that Sir C. BELL had recourse to this local application of the strong caustic solution in a case under his care; and remarks in his Lectures as follows on the practice: "It is said that a little practice will enable a person to pass his finger into a patient's throat, and to familiarize his sense of touch with the ordinary condition of the upper part of the respiratory apparatus, so as to be able to detect swelling, or irregularity, or thickening about the chink of the glottis. And great advantage is said to have been obtained from applying remedies directly to the diseased or irritable part. This practice was much followed by the late Mr. VANCE, who had been for many years a naval surgeon; and he called it, in naval phrase, *swabbing* the affected organ."\*

\* As the question of priority in regard to local applications to the larynx has given rise to some discussion, and is alluded to by Dr. LAYCOCK and our author, it is proper to state the principal facts relating to the subject. There can be no doubt that Sir CHARLES BELL and Mr. VANCE were in the habit of making local applications to the inner surface of the larynx with the sponge and probang, much after the manner of Dr. GREEN. The statement that "Dr. GREEN, several years before the appearance of Messrs. TROUSSEAU and BELLOC's book, had instituted experiments, and come to a similar conclusion," is quite erroneous. The work above mentioned was published in Paris in the summer of 1837, and was reviewed by Dr. JOHNSON in the October number of his *Review* for 1837, and the January number of 1838. In the summer of 1838, Dr. GREEN had a conversation in London with Dr. JOHNSON on the subject of the treatment of laryngitis, "and the suggestion was made," says Dr. G., "that if proper applications could be applied below the glottis, no difficulty would occur in successfully treating the disease. Acting upon this suggestion, after my return home, I made the attempt, and was successful in entering the larynx, and thereby succeeded in curing a well-marked and severe case of laryngeal disease. With the like success other cases were treated in the same year, and the appearance of the TROUSSEAU and BELLOC soon after, confirmed my confidence in a method of treatment which I have since pursued," &c. (*Preface to Treatise on Diseases of the Air-Passages, &c.*, New York, 1846.) Dr. G. probably refers to the *American Translation of Trousseau and Belloc*, which appeared in 1841; the original work, however, we have seen, was published four years, and reviewed more than three years before this period. It is to be remembered, moreover, that these authors do not claim to have entered the larynx with the probang and sponge, and TROUSSEAU has expressly disclaimed it in a published letter to Dr. GREEN. The similarity of their modes of procedure will appear, however, from the fol-

361. Where the laryngeal complication occurs in the advanced course of phthisis, this practice can prove only of temporary benefit. I have been consulted in many cases of this description where it had been said to have been resorted to, but apparently either with no advantage, or with very temporary relief. However, in idiopathic or primary cases, or when the complication occurs in an early stage of phthisis, for which a rational and an appropriate treatment is prescribed, this local medication of the laryngeal complication may be employed, by one capable of performing it, safely and satisfactorily. I do not, however, believe that the appliances here advised enter the larynx and trachea once in twenty times; whatever benefit results arises from the applications to the under surface of the epiglottis and adjoining parts. I have, since the commencement of my practice, trusted much in those cases to the inhalation of the weak vapour of turpentine arising from the application of the embrocation so often mentioned, either around the throat and neck, or to the chest, or between the scapulæ.

[In this connexion, we should bear in mind that diseases entirely located in the larynx or pharynx are often mistaken for pulmonary tuberculosis; that even when tubercles exist, the more prominent symptoms may be owing to the pharyngeal and laryngeal complications; and that these complications may be greatly alleviated, or even removed, by local treatment, and in this way, as suggested by Professor BENNET, thus tend to arrest the pulmonary disease. Dr. HORACE GREEN has extended topical medication in pulmonary diseases to the injection of a solution of nitrate of silver into the bronchial divisions by means of a gum-elastic tube or catheter passed down the trachea. In the volume of *Transactions of the American Medical Association* for 1856, he has reported over one hundred cases of pulmonary and bronchial disease treated in this manner. Of these, 71 were stated to be cases of *tuberculosis*, and 32 cases of *advanced phthisis*, in which cavities were recognised in one or both lungs; 39 were reported cases of *incipient phthisis*. Of the first division, *advanced phthisis*, 14 died, 25 were said to be more or less benefited, and 7 not benefited by the injection. Of the 39 cases *incipient tuberculosis*, 12 apparently recovered, and 5 convalescent at the time of making the report (May, 1856). Of the remain-

ing 22 cases, 17 "have been greatly improved, 3 moderately benefited," and 3 only failed to find relief. Of the 28 cases of *bronchitis*, 16 were reported as cured; all the others had been greatly benefited, though some were still under treatment.]

362. *D. The Abdominal Complications* of phthisis have been already partly considered, when remarking upon the treatment of the diarrhoea (§ 328), and of the impaired digestion and assimilation (§ 234) so generally observed previously to, and in the course of the malady. But the functions of the liver are also not sufficiently discharged in the course of the disease; and due attention has not hitherto been directed to them. That this organ has been long disordered in cases of phthisis is shown by the nature of the organic lesions it generally presents after death (§ 118). It has been insisted upon by an able and close observer of the causes and nature of disease (Dr. McCORMAC, of Belfast), that phthisis is not only caused, but is also perpetuated, by an imperfect supply, and an insufficient digestion and assimilation of pure air in and by the lungs; consequently, the red globules of the blood are not oxygenated and assimilated to such an extent or amount as to supply the requisite materials by their waste for the elaboration of healthy bile: owing also to this cause, the carbonaceous and hydrogenous elements are not sufficiently combined with the oxygen of the respired air, so as to contribute to healthy assimilation and nutrition; and they consequently, under the influence of life, form morbid or adventitious products, and give rise to the fatty enlargement of the liver so generally found after death (§ 118).

363. The great importance of promoting the digestive and assimilating processes from the very commencement of phthisis, whatever other means of treatment be adopted, will appear from what has been advanced above; and I know of no surer means of attaining this end, than by improving the secretions and excretions by suitable medicines and food, and by removing the patient to a high, dry, and temperate air, where he may enjoy the advantages of sunshine and exercise, and avoid those causes which reduce organic nervous or vital power. In general physicians have been, during the last half century, in which such wonderful advances have been made in the practical sciences, so much occupied in listening to sounds which they often could neither interpret nor refer to their proper sources—in splitting the diagnostic hairs floating before their troubled, if not always dazzled vision, and in hearing what they believed even when not believing what they heard—as to be carried along by the pathology in fashion, neglecting those great views of physiological pathology which alone furnish the true basis of rational and successful practice. While a murmur, a bruit, a râle, a ronchus, and every sound for which a term could be coined, and their various grades, cadences, &c. were observed, or were feigned to be observed, and were noted, and paraded and admired, on all occasions, the conditions of the vital powers and functions, upon which both disease and recovery from disease mainly depend, were entirely neglected. But attention to these latter, to the states of the secretions and excretions, to the manifestations of impaired vital power, to the causes of this impairment, to the removal of those causes, and to the true means of restoring lost energy, as regarded

lowing quotation from Messrs. T. and B.'s work (*Am. Trans.*, p. 125):

"When we wish to cauterize the pharynx, the base of the tongue, and the top of the larynx at the same time, we take a whalebone at least a line and a half thick, that it may not bend readily; this is heated an inch or more from one end, and, when sufficiently softened, we curve it at an angle of 45°. To this end we fasten a spherical piece of sponge six lines in diameter; the sponge is to be moistened with a solution of nitrate of silver, the mouth opened, and the tongue depressed. When the isthmus of the gullet is passed, there occurs an effort of deglutition which elevates the larynx, and we seize this opportunity to draw forward the sponge, which had been at the entrance of the œsophagus. By this manoeuvre we get at the glottis, and then it is easy to express the solution into the larynx; the cough which now occurs favours the introduction of the caustic," &c. Dr. GREEN, instead of a spoon, uses a broad spatula, bent at right angles, and instead of "expressing the solution into the larynx," passes the sponge directly into the cavity. To him, therefore, undoubtedly belongs the credit of establishing the possibility and utility of the direct introduction of nitrate of silver into the laryngeal cavity; just as Dr. MORTON proved the safety and advantage of the inhalation of ether as an anæsthetic, although it had been suggested and used occasionally by others for similar purposes.]

a malady the most fatal, the most prevalent, and the most constant in its prevalence, was practically discarded; and fussy manipulations, striking examinations—where such examinations and manipulations were often unnecessary—were paraded in the place of these, and of other more profound, more physiological, and more practical investigations.

364. *E.* Several other complications, of less frequent occurrence than the above, have been mentioned (§ 119–123), but the means appropriate to each will readily suggest themselves to the physician. *Edema* of the lower extremities (§ 120) not unfrequently occurs in the advanced stages of phthisis, and is sometimes diminished by prescribing small doses of bicarbonate of soda, or of potash, with the tonic infusions or the diuretics, or with the means employed for the disease. Pressure on the course of the veins of the lower extremities, by the sitting or other posture of the body, sometimes favours the *œdema*, and even occasions a permanent obstruction of these vessels.

365. xii. BRIEF REMARKS ON SOME OF THE MEANS ADVISED FOR TUBERCULAR PHTHISIS.—Having considered the treatment which appears the most suited to the several forms and stages of phthisis, I am next desirous to notice the medicines which have been recommended by writers for this disease, and to mention the circumstances or states of the malady in which they may be prescribed, and in which they are contra-indicated. Most of these medicines have been prescribed empirically in phthisis; for, although the treatment of the disease had assumed a rational aspect in the works of our countrymen BENNET and MORTON, there were few besides, even among the most eminent of medical writers, who presented us with a plan of cure which was even tolerably appropriate to the stages and states of the disease; and, even among those who had cultivated the most the diagnosis and pathology of this malady, there were very few who recommended their favourite remedies with due reference to the states and complications of the disease, and to the pathological conditions which they had themselves described or admitted. I shall, therefore, attempt to inquire, in my brief notices of the substances recommended, into the circumstances in which either experience or the operation of these substances warrants their use.

366. *Acids*.—Most of the *mineral and vegetable acids* have been employed in phthisis, but seldom with any definite object, or to fulfil a rational indication. The chief intention with which they have been prescribed in recent times is to repress or prevent hæmoptysis, or to act as a refrigerant when the febrile action is considerable, and the night-sweats exhausting. They are merely palliatives—and in this they often fail, and sometimes they even render the cough harder and more severe; and, with the exceptions of the hydrocyanic and boracic, they are injurious to the sub-inflammatory states, and in the inflammatory complications of the disease. The *acetic acid* has long been employed in phthisis, and when the contra-indications just mentioned do not prevent recourse to it, either simply or in the form of raspberry-vinegar, or oxymel more or less diluted, it is a grateful and cooling medicine, especially after hæmoptysis has been considerable or excessive. In states of great exhaustion or colliquation, when it is desirable to produce an antiseptic as well as an astringent effect, the pyroligneous

acetic acid may be given, or even a drop of the aromatic.

367. *Sulphuric acid*, much diluted, has been commonly prescribed in phthisis, and generally with the same object as the acetic. BANG gave it with mucilages; JOERDENS with the *Phelandrium aquaticum*, a medicine much employed in Germany for this disease, and PORTAL in states of weak dilution, as a cooling drink; ROLLO and HUFELAND considered it useless; but COLLBATCH, GRANT, DE HAEN, HOME, FOTHERGILL, SIMMONS, SIMS, and MARX, entertained a more favourable opinion of it, especially in the form of *acidum sulphuricum aromaticum*, or *vitriolic elixir*. QUARRIN very justly cautions against its use in the more inflammatory states and complications of the disease. Weak dilutions of the *nitric* and the *hydrochloric acids* may be prescribed, in the same states as those which admit of the use of the foregoing; and the combination of the two—one part of the former to two of the latter—when the contra-indications mentioned above are not present; and when exhaustion, colliquation, and other symptoms of vital depression are urgent, these two may be added to the infusion of cinchona, or other restoratives, especially when the functions of the liver are much impaired. I have prescribed them with benefit in such cases, and sometimes given the cod-liver oil on the surface of a mixture of these or of similar substances.

368. *Hydrocyanic acid* is one of the most useful medicines in this disease. It was introduced into practice by MAGENDIE, GRANVILLE, and ELLIOTSON, who took a just view of its effects both in phthisis and in dyspepsia—complaints so intimately allied in their origins and in their pathology, as already shown. Its influence in the latter benefits the former, while it exerts a soothing effect on the cough, without aggravating, but rather ameliorating, any complication which may appear in the course of the malady. It may, moreover, be advantageously conjoined with other acids, with the neutral salines, most of which it is incapable of decomposing, and with the great majority of other medicines usually prescribed for phthisis. Of the other acids, the most important are the *citric*, the *benzoic*, and the *boracic*. The *citric* is serviceable in the states of the disease for which the acetic is given; but, either in the pure form or as it exists in lemon-juice, it is most useful as an adjunct to beverages, or in combination with the alkalies. In these latter states it aids, with other means, in preventing, counteracting, or removing the morbid conditions of the circulating fluids in the advanced stages of phthisis. *Benzoic acid* has been frequently advised in various combinations for this disease, but has rarely been confided in alone. It is chiefly in the more asthenic and colliquative conditions that it is at all of service. I have seen more benefit from the *boracic* than from benzoic acid. Either of these acids may be given conjoined with mucilaginous, balsamic, and expectorant medicines, when these are indicated. The boracic acid and its alkaline salts—the bicarbonate of soda and B. of potash—are not contra-indicated by the inflammatory diathesis, and may be given in those states in which the mineral acids are inappropriate. I have found the *dilute phosphoric acid* of much service in the few cases in which I have tried it. It may be prescribed in doses of 20 to 40 minims in cases of phthisis characterized by vital depression or exhaustion, especially when

the disease appeared to result from depressing causes, or from masturbation. For such it may be given in the infusion of absinthium, or of ginseng root, with or without the addition of the tincture of sumbul.

369. *Aconite* was first prescribed for phthisis by PORTAL, who afterward relinquished the use of it. BUSCH gave the powder of the dried leaves in doses of two grains every two or three hours, and increased the dose until a drachm was taken in the twenty-four hours. I have prescribed the powder in smaller doses in a few cases, and the extract in doses of a quarter of a grain in others, cautiously increasing the dose; but I have ventured upon it only in the more inflammatory states as a substitute for bleeding. I cannot say that it was so beneficial as BUSCH and HAREL DU TANEL have stated it to have been. It had, however, the effect of lowering the pulse, of causing perspiration, of diminishing pain, and of affording ease; and although I cannot view it, with the writers just mentioned, as a cure for phthisis, yet I consider it as an excellent medicine in the more inflammatory states and complications of the disease, when prudently exhibited, or when its doses are increased, or its use interrupted and resumed from time to time, as circumstances require.

370. *Alkalies and alkaline salts* are serviceable in several states of phthisis. The former, and their sub-carbonates, were much praised by BARKER and SPALDING. I have often prescribed the liquor potassæ and BRANDISH's alkaline solution in the serofulous forms of the disease, with sarsaparilla, demulcents, and nareotics, and, in the protracted form, with tonics or bitters and anodynes, with temporary, and sometimes with permanent benefit. In certain states, and more particularly when the blood is probably more or less contaminated by the passage into it of morbid matters from the lungs, the alkalies are often advantageously combined with the solutions of the neutral salts, as the bicarbonate of potass with the nitrate, or the solution of the acetate with the carbonate of ammonia, and with the other substances now mentioned.

371. *Ammoniacum* was frequently prescribed in phthisis, and often injudiciously, especially in combination with squills or other heating gum-resins. It should be given only in the more chronic states of the disease, and even in these with caution, and rarely with the medicines now mentioned. I have prescribed it with benefit when an expectorant was required, and when no inflammatory complication existed; but if the cough became severe or hard during its use, it was always relinquished. I generally gave it as follows:

No. 359. R Ammoniaci, ʒjss. tere cum Aq. Destill. ʒivss.; dein adde Vini Antimonialis, ʒij.; Liq. Ammoniac acetatis, ʒij.; Tinct. Conii (vel Tinct. Hyoscyami), ʒij.; Syrupi Altheæ officialis ad ʒviij., miscce. Sit mistura, cujus capiat cochl. j. vel iij. largā, 4tis vel 6tis horis.

No. 360. R Ammoniaci, ʒjss.; Tinct. Benzoini Comp., ʒij.; Tinct. Camphoræ Comp., ʒss.; Aquæ Flor. Aurantii, Aq. Sambuci, ʒā, ʒiij. Tere bene, et adde Tinct. Conii, ʒjss.; Acidi Hydrocyanici diluti, ʒss.; Syrupi Tolantii, ʒij.; Syrupi Altheæ officialis ad ʒviij. Miscce. Capiat cochl. j. amplum, 3tis vel 4tis horis.

No. 361. R Ammoniaci, Balsami Sulphuris Anisati (vide § 400), ʒā, ʒj.; Extr. Hyoscyami (vel Conii), ʒij.; Saponis Castil., ʒss.; Extr. Glycyrr., ʒss. Miscce. Fiant, secundum artem, Pilulæ L. quarum capiat unam vel duas, omni 4ta vel 6ta hora.

No. 362. R Ammoniaci, Galbani, Extr. Conii, Saponis Castil., ʒā, ʒss.; Fol. Belladonnæ, gr. xv.; Antimonii Potassio-tart., gr. v. Contunde bene, et fiant secundum

artem Pilulæ xxxvj. Sumantur binæ vel tres ter in die. (The Pills prescribed by RICHTER (*op. cit.*) for tubercular phthisis.)

372. *Balsams* have been long in use in chronic pectoral diseases, and especially in phthisis; and although they are sometimes of service, they are as often injurious, unless they be given with great discrimination. Under this denomination the *Copaiba*, the *Peruvian*, and the *tolu balsam* fall more strictly; the others more correctly belong to the terebinthines and to the gum-resins, and to these likewise the older writers often extended the term. The circumstances and the combinations in which the balsams, and even the other substances often ranked in the same category, may be prescribed in phthisis, are the same as those which I have stated in respect of the exhibition of ammoniacum (§ 371). When it is considered that these medicines, and those closely allied to them, are appropriate only in certain states of the malady, that an empirical use of them may be as often injurious as beneficial, we should not be surprised at finding them recommended by DE HAEN, GODBOLD, SIMMONS, RUSH, &c.; and denounced by FOTHERGILL, FRIZE, and others. The *Copaiba balsam* was preferred by FULLER, HOFFMANN, MONRO, and GESSNER; but it is now seldom prescribed for phthisis. A substance becomes a remedy only by its appropriate use.—*Barytes*, the *hydrochlorate*, has been recommended in phthisis by HUFELAND, HERZ, and CRAWFORD; but although it has been prescribed by many, yet no satisfactory result has been adduced respecting it.

373. *Bitters and tonic infusions*, as those of absinthium, Gentian, Calumba, Chereita, &c., have been advised for phthisis by CÆLIUS AURELIANUS, CHALMERS, SALVATORI, RUSH, MAY, and PEARS, generally also with a nourishing and digestible diet. Although too generally and empirically prescribed by these and other writers, yet these medicines are often required in the usual and more chronic states of the disease, especially with the view of removing the symptoms of indigestion so frequently attending phthisis from its commencement, and of supporting the vital powers. These infusions, moreover, may be made the vehicles in which other medicines, whether saline, anodyne, or alternative, or nareotic, may be prescribed.

374. *Camphor* was given in phthisis by BURNERIUS; by MARX, with nitre and hydro-chlorate of ammonia; and by KORTUM with this latter salt. It is useful chiefly as an adjunct to other more appropriate medicines, or when it is given with the object of abating urgent symptoms. In small doses it is beneficial, especially when conjoined with nitre, the spirits of nitric ether, and a solution of the acetate of ammonia, in allaying febrile action and inflammatory complications. In larger doses, and combined with the sesquicarbonate of ammonia, it is of service in the advanced stage of phthisis, in rallying the vital power and in counteracting morbid conditions of the blood, while it promotes expectoration; and with the extract of conium or of henbane, or with a preparation of opium, it allays irritation, both locally and generally.

375. *Carbon or charcoal* was formerly much employed in the colliquative states of phthisis, in dysentery, and in putro-adyynamic fevers. I have given it at an early period of my practice in several cases, but generally with camphor, chalk, cascarilla, and aromatics, in doses varying from a

scruple to a drachm, and chiefly with the intention of correcting the fetor of the excretions. SOBERNIEM states that SCHÖNLEIN gave it in phthisis with digitalis; and GARRETT prescribed it with sulphur and the extract of the smaller centaury. I suspect, however, that whatever benefit resulted from these combinations cannot be imputed to the carbon. M. JOURDAN justly remarks, "Lorsque les théories chimiques régnaient en Médecine, on attribuait au Charbon végétal puissantes vertus dans la phthisie pulmonaire, la dysenterie, et surtout les maladies putrides. Le temps n'a justifié aucune des espérances qu'on avait conçues à cet égard."

376. *Cascarilla* was often prescribed with the same intention as cinchona and the medicines last noticed. I have given it only in the form of infusion in the more colliquative states and non-febrile forms of phthisis, and have generally made this preparation the vehicle for such other medicines as the peculiarities of the case suggested. *Cascarilla* has received the approbation of THULENIUS, WENDT, KRUGELSTEIN, and HECKER, in the usual and more chronic forms of the disease, indeed, in the states for which I have prescribed it. The historical sketch I have given above will sufficiently show the diversity of opinions as to the propriety of employing the tonic and astringent barks in phthisis, and more particularly as to the use of cinchona, &c.

377. *Chalybeates* have been already mentioned in connexion with the states of the disease in which they may be prescribed. They have been recommended by GRIFFITH, GÜNTHER, STANGER, SCHULLER, VELSEN, and many others. The compound mixture of iron, the ammonio-citrate of iron, the ammonio-chloride of iron, the solution of the pernitrate of iron, the potassio-tartrate of iron, the tinctures of the acetate and of the murate of iron, and the compound pills of iron, are severally of use in certain states of phthisis; but there are few medicines which require greater discrimination and caution in their use in this disease than they. Cases which proceed from depressing and exhausting causes, in which the blood is poor in red globules, or which are free from inflammatory or hæmoptysic complications, are often benefited by chalybeates, as well as by other tonics, especially if dyspeptic symptoms are prominent; but their effects upon the cough, expectoration, breathing, pulse, and the accompanying hectic, should be carefully watched; and any aggravation of these should cause the discontinuance of the medicines and the adoption of other means. The good effects of chalybeates may be aided by other medicines, with which they may be conjoined according to the stage and complications and other peculiarities of the case.

378. *Cinchona*.—While DESAULT, DE MEZA, and ROMANS considered it injurious, and FOTHERGILL said that it was rarely of use, QUARIN, VOGEL, RAULIN, MARX, JAEGER, HORN, SCHMIDTMANN, and others, recommended it. HALLER, HOME, and CHAPMAN prescribed cinchona with a milk and vegetable diet. CALLISEN gave it with a powerful stimulant, the oil of asphaltum, of which notice will be taken hereafter; THOMANN with opiates; and RYAN and MAY with animal food. STOLL advised cinchona, when inflammatory symptoms were absent, and SIMMONS when the expectoration was abundant and puriform. METTERNICH preferred the extract, and gave it in large doses. In more recent times, the *sulphate*

of *quina* has been substituted for the preparations of cinchona, in phthisis as well as in other diseases; but I doubt the advantage of the substitution as respects this malady, for the infusion, the decoction, the extract, and the compound tincture of cinchona, furnished the physician with the means of selection according to the features of the case for which he was prescribing. However, the sulphate of quina is an excellent medicine, when it is desirable to have recourse at the same time to an acid and to an astringent; and then it may be given in the compound infusion of roses, and at the same time also, as advised by GUENTHER, AMELUNG, DROSTE, and some other German writers, with the tincture of digitalis, or with the powder of digitalis in the form of pill. I have prescribed it with small doses of camphor and conium, with benefit in some states of the disease.

379. *Conium* has, from the days of STÖERCK down to the present time, been more generally employed in phthisis and scrofula than perhaps any other medicine. It has been praised by QUARIN, ZEVIANI, FOTHERGILL, ADAIR, BUTTER, BUSCH, HUFELAND, and many others; and yet there are few medicines whose effects in phthisis are more equivocal, and, as usually employed, are more uncertain. At the present day it is seldom confided in alone; and when given as an adjunct to other means it is often in insufficient doses, or in imperfect states of preparation, and not persisted in for the time required to evince its effects.

380. *Creasote* has been recommended for phthisis by SCHROEN, REICHENBACH, CARTONI, RAMPOLD, and others. I have employed it, since its introduction to medical practice, chiefly as an adjuvant of other means in the last stage of the disease, and for the mitigation of the disorders of the stomach and bowels—of nausea, vomiting, diarrhoea, &c. It is also of great benefit when used to slightly impregnate the air of the apartment in which the patient chiefly resides (§ 413). *Creasote*, however, should not be prescribed in the circumstances contra-indicating chalybeates and tonics—when the cough is dry, hard, or constrictive—when a state of erythema or of active congestion is inferred, and when an inflammatory complication or active hæmoptysis is present. It is chiefly in the colliquative or asthenic conditions of phthisis that it is a valuable adjunct of other means, and especially when the excretions are more or less fetid, and the circulation is contaminated by the passage of morbid matters into it from the primary seat of disease.

381. *Digitalis* has been recommended by some, and praised by others, for phthisis. Indeed there is, perhaps, no other medicine which has been more generally employed in this disease, and whose operation has been less understood, than digitalis—has, in short, been more empirically prescribed. It has been sanctioned by BEDDOES, WITHERING, DARWIN, FERRIAR, SPENCE, FOWLER, KINGLAKE, MAGENNIS, MEYER, and THOMAS. Dr. DRAKE says that citric acid counteracts its unpleasant or cumulative effects, when given in too frequent or too large doses. While the above, and many continental writers, are favourable to the use of digitalis in phthisis, BREE and BAILEY contend that it is injurious in some cases and useless in others. I have, however, seen some benefit derived from the infusion, prescribed at first in very large, and afterward in rapidly

diminished doses; especially in the hæmoptysic and febrile states, and in the congestive and inflammatory complications of the disease.—*Dulcamara* was advised for phthisis by BURSERIUS, and afterward by STARK, RICHTER, and HUFFELAND, who generally gave it in conjunction with the Iceland moss.

382 *Emetics* have been recommended for phthisis since the days of HIPPOCRATES to the present time. MORTON, BRYAN-ROBINSON, MARRYAT, SIMMONS, SIMS, KENTISH, MARET, REID, METTERNICH, SWEDIAUR, PARR, RICHTER, DUMAS, &c., advise emetics at an early stage of the disease; some, as REID, BAYLE, and others, with a frequency which appears to be excessive or even injurious; others, as YOUNG, CLARK, WITT, &c., in a more moderate and rational manner. Many physicians in Italy, early in the present century, pretended to have cured phthisis by the exhibition of a solution of tartar emetic, in the infusion of the flowers of the *sambucus nigra*, or in other emollient infusions—generally three grains of the former in six ounces of the latter. A quantity sufficient to produce vomiting was directed night and morning, and milk and water were drunk freely. If diarrhoea supervened, digitalis and ipecacuanha were prescribed in small and frequent doses, with other means calculated to moderate or arrest the diarrhoea, and the emetic tartar was relinquished.

383. Emetics are often of service, especially in the early stage of the malady, and when advised as above (§ 306, 317); but they should be prescribed with caution, and with strict reference to the functions of the stomach and liver, and to the assimilative and vital powers. I have already mentioned those which may be preferred; but even they ought not to be given so as to impair digestion and assimilation; and if these functions be weakened by them, or in cases where this risk appears great, mild tonics and a restorative and digestible diet, aided by external derivation, should be prescribed. In the advanced stages of phthisis, emetics are of more doubtful advantage, but even in these they may be of service. BLUMENBACH recommended them even in the third stage; but either in this or in an earlier period, they sometimes constitute an important part of rational practice, especially if appropriately selected, when the digestive mucous surface appears to be loaded by sordes, when the expectoration is difficult or scanty, the breathing suffocative or oppressed, and the biliary secretion interrupted, or deficient in the evacuations. But even in these circumstances, vital power should not be exhausted by a too frequent recourse to them, and the digestive functions ought to be restored soon afterward by suitable tonics and anodynes, as the infusion and tincture of calumba, or of chereita, or of other bitter tonics, with hydrocyanic acid, conium, &c.; or with one of the vegetable extracts, the purified ox-gall, &c., in the form of pill. *Ipecacuanha* is useful in phthisis not merely as an emetic, but as a nauseant, expectorant, and promoter of digestion, and as a corrector of morbid actions in the bowels, according to its dose and mode of administration. As a nauseant it was praised by PIDERIT, BARBARI, and others; and it certainly is a valuable medicine in the more inflammatory and hæmoptysic states of the disease; and in the form of pill with bitter tonics and anodynes, or astringents when the bowels are much relaxed.

384. *The iodides*, especially the iodide of potass,

have been employed in phthisis, but are appropriate only in the more chronic states of the disease. Since the discovery of iodine, the use of its preparations in scrofula had extended to tubercular consumption. The earlier prescribers of this substance, and of iodides generally, erred in giving them in too large doses, in scrofulous and other diseases, and in neglecting to conjoin them with a sufficient quantity of alkalies, whereby the irritating effects of the iodine, or the decomposition of the iodide, by the acids of the stomach, might be prevented. Thus, even when a very small dose of the iodide of potass is prescribed in a vehicle suited to the features of the case, the solution of potass or the bicarbonate should be given in sufficient quantity to prevent the decomposition of the iodide. Whatever form or combination of iodine is given in phthisis, the effect upon the digestive functions, the pulse and the cough should be watched, and if it induce dyspeptic symptoms, or aggravate those already present, it should either be relinquished, or the dose of it much reduced. *The Karageen Moss*, or *Fucus crispus*, has been long employed as a popular remedy in consumption, and it has been favourably noticed by M. BÉRAL, myself, and others. It, as well as others among the fuci, may be used as a demulcent in this disease, with some benefit, probably arising in part from the minute quantity of iodine this class of sea-weed contains.

385. *The Lichen Islandicus* has been very commonly used in consumptive cases by QUARIN, BERGIUS, THILENIUS, MARX, RÉGNAULT, RICHTER, SCHMIDTMANN, CHRIGHTON, and others. It is one of the most generally useful medicines in this disease; its bitter, demulcent, and tonic properties, divested of exciting action, rarely proving injurious, even in the most febrile cases. WENDT, myself, and others, prescribed it with milk, adding to these such other medicines as the circumstances of the case required. SACHTLEBEN recommended a decoction of three ounces each of the lichen, and of the *polygala amara*, of six drachms of liquorice-root, and of three drachms of *dulcamara*, to be made with milk, as a preferable mode of prescribing the lichen in consumption. The decoction of these substances is best made with water to which a small quantity of the carbonate or solution of potash is added, boiled milk being added to the strained decoction, and such anodynes or other remedies as the peculiarities of the case suggest.

386. *Lactucarium* was much employed by DUNCAN, ROTHAMMEL, and FRANÇOIS to allay the cough in phthisis and bronchitis, and was considered appropriate in the inflammatory state of the disease. It may be given under almost any circumstances with this intention, and may be conjoined with the ipecacuanha, digitalis, demulcents, mild tonics or bitters, or other medicines suited to the case.

387. *Lead, the acetate of*, has been often prescribed in phthisis, but chiefly with the view of arresting hæmoptysis, and it has then been given either with opium and ipecacuanha, in the form of pill, or in solution, with the addition of acetic acid. These combinations of acetate have been advised by KOPP, STARK, ETTMÜLLER, AMELUNG, HILDEBRAND, HORN, and others. WEBER prescribed the acetate with digitalis, myrrh, balsam of Peru, extract of hellenium, and mucilage, in the form of pills. HOFFMANN preferred the

phosphate of lead, in the dose of a grain, to the acetate, and conjoined it with the extract of henbane.

388. *Lime water* and the *muriate of lime* were advised by QUARIN, MARX, BEDDOES, and HUFELAND. Effervescing lime water (*Carara water*) is very advantageously given with milk, especially when the bowels are much relaxed. For this state of the malady not only may catechu, kino, and other means already recommended for it, be employed, but the nitrate of silver, the extract of nux vomica, tar made into pills with liquorice powder, &c., also be individually tried.

389. *Mercurials* are occasionally of service in phthisis, especially in certain states of the disease, and when judiciously combined with other medicines. Mercury with chalk, the blue pill, or Plummer's pill, will be of service, when the biliary functions are torpid, either alone or with soap and taraxacum, or with the compound rhubarb pill, or with the aloes and myrrh pill, when the digestive functions require to be assisted. In the more inflammatory states or complications of the disease calomel may be prescribed, as advised by BEDDOES; although it should not be pushed so far as to produce salivation, as recommended by RUSH, unless the disease be consequent upon syphilis; when the very unfavourable state of the malady may require this decided treatment. When partial pneumonitis, or pleuritis, or pneumo-pleuritis complicate phthisis, then calomel may be employed, and be beneficially conjoined with antimonials, or with ipecacuanha, or with opium, or with other narcotics. The beneficial effects of the bichloride of mercury, prescribed in the decoction, or in either of the tinctures of cinchona, in scrofulous cases, have induced me, as well as other physicians, to employ the same combination in the more manifestly scrofulous states of phthisis, and in some instances with much benefit; but in my own cases, as other means were also employed, especially the external treatment about to be noticed, the amount of benefit derived from the former could hardly be determined. SCHAEFFER and VALENTIN have also given the bichloride with tonics and opium in phthisis, and, as they conceived, with advantage.

390. *Myrrh* and various gum-resins, especially *asafoetida*, *galbanum*, &c., are most appropriate in the more chronic or protracted forms of phthisis, when they are attended by dyspnoea or difficult expectoration, and in females when the catamenia are difficult or scanty, or when the disease has been caused by depressing or exhausting causes. They are contra-indicated during inflammatory states and complications, and in the febrile forms of the malady; and are best suited to the circumstances of the disease which admit of chalybeates, tonics, balsams, cinchona, &c. In the form of GRIFFITH'S mixture (§ 314, 377), or when conjoined, as in the compound galbanum, or compound iron pill, or when farther combined as with soap, extract of conium, or extract of henbane, they are sometimes of service.

391. *The oils*, especially *fish oils*, have only recently been employed in consumptive diseases, although they have been long previously used in other disorders. HANKEL appears to have been the first to prescribe the *cod-liver oil* in phthisis in Germany, and Professor BENNETT in Edinburgh, to whom the credit of having first recom-

mended it is clearly due. Contemporary with the earliest employment of it in this country, it was prescribed for a lady, whom I frequently saw in consultation with my friend Dr. BAIRD; and at that time it was not to be had in London, Mr. MORSON having procured it, at our request, from the continent. Since then I have employed it in this and several other diseases, and have always seen more or less benefit derived from it, especially in the more usual, and in the protracted states of phthisis. It may be given in various ways; but generally with greatest benefit, from an hour to two hours after a meal, in the dose of half an ounce or even more for an adult, on the surface of any agreeable vehicle, as of an infusion of orange peel, or of any bitter tonic or aromatic infusion, with either a little acid or carbonate or citrate of an alkali, and any anodyne, &c.; or on the surface of milk, or of ginger or orange wine, &c. This oil may be taken twice or thrice daily, and in all stages of the disease. After continuing it for some days or weeks, it may be intermitted for a few days, and medical treatment may then be directed more especially to the digestive functions, and to the promotion of the biliary and intestinal secretions and excretions; and after such intermission, its use should be resumed and continued for a time which the state of the case and its effects will indicate.

392. All the *fish oils*, especially the oils from the livers of the *Torsk*, *Cod*, and other fish which I have enumerated above (§ 336), are beneficial in phthisis, especially when they are recent or fresh, and then they may be taken in larger quantity. The common use of fish oils in the most northerly countries of Europe probably is partly the cause of the infrequency of phthisis in those countries. The use of vegetable oils, especially *olive oil*, in countries near the Mediterranean, and in the north of Africa, may have the effect of diminishing the number of phthisical cases in those countries; and the adoption of the *palm-oil nut*, as an article of food, in Western Africa, and of the oil for daily inunction of the surface of the body, may have a similar effect on the natives of that part of the world. It is not unlikely that other mild vegetable oils, as *linseed*, *almond*, &c., may also prove of service when taken in sufficient quantity, and when judiciously conjoined with other medicines. Formerly the *oil of asphaltum* or of bitumen was often prescribed for phthisis, especially by CALLISEN, BANG, THILENIUS, HEALDE, and others. QUARIN said that it was only slightly palliative, while FRIZE considered it injurious. It was probably employed then, as other things have been used recently, or are praised now, merely with the object of being, with their abettors, talked of.

393. *Opium* and *Opiates*, in various forms, have been advised in phthisis by many writers, and condemned by others. There are, however, states of the disease which indicate the propriety of having recourse to them, and circumstances which contra-indicate their use. They are more frequently injurious than beneficial in the first stage of the disease, although TRALLÉS has given a different opinion. Sometimes in the second stage, but most frequently in the third stage, opiates, or even the preparations of morphia, are of great service; but much of the benefit produced by them will depend upon the combinations in which they are prescribed. MARCUS gave them with myrrh and Peruvian balsam,

and, in the advanced and more chronic states of phthisis, this combination, or that with the compound galbanum pill and the compound soap pill, will be appropriate. PEART advised opiates to be given with the carbonate of ammonia, ether, and aloes; and J. FRANK laudanum, with the aromatic sulphuric acid. In the third stage of the disease, preparations containing more or less opium, especially the compound tincture of camphor, the compound styrax pill, pills of ipecacuanha and opium, &c.; and, when diarrhoea is present, the opiated cretaceous powder, the compound cretaceous powder with opium, the compound ipecacuanha powder, the compound kino powder, or the combination of opium with the extract of nuxvomica, or with the nitrate of silver, or with the sulphate of copper, or with the sulphate of zinc, will be found individually of service, when judiciously prescribed. When there is much debility, opiates should not be given in full doses, unless they be combined with aromatics, tonics, or stimulants, or with balsams or gum resins; and when the preparations of morphia are preferred to other opiates, then this recommendation should be especially kept in recollection, because I have seen much distress result from its neglect.

394. *The Phyllanthium aquaticum*, or water hemlock, especially the seeds and herb, has been much recommended for phthisis by STERN, OSWALD, FISCHER, J. FRANK, RICAMIER, ROSEN-MÜLLER, HENNING, MICHAELIS, &c., who have employed chiefly the powder of the seeds, in doses of ten to twenty grains, the decoction and tincture. Its action is stimulant, narcotic, and diuretic. Some of the authorities now adduced have given this medicine with sulphur. LANGE prescribed it after bleeding, in robust or plethoric cases, in goats' milk twice or thrice daily; HERZ, with nitrate of potass, sugar of milk, and gum Arabic, thrice daily; and HUFELAND, MÜLLER, CHIAPPA, RENER, BERKUN, and HEINE, in various forms and combinations—in powder, decoction, and tincture.

395. *The Polygala amara* has been much praised in phthisis by THILENIUS, PLENCIZ, COLLIN, BAUME, FRIZE, &c., and is certainly to be preferred to the *Polygala senega* in this disease, as it is more tonic and pectoral than this latter. It was formerly much employed in consumptive diseases, but has now fallen into undeserved neglect. The root is chiefly used; and either in powder (from fifteen to thirty grains), or in extract or infusion, or decoction, in which forms it is directed in several of the Continental pharmacopœias. The *Polygala Senega* is much more stimulating than the *P. amara*, and is not appropriate in the more inflammatory and complicated states of phthisis, unless it be given with ipecacuanha, or with antimonials, so as to occasion nausea or vomiting. The decoction is, however, sometimes of use, not only when prescribed with this intention, but also in the less febrile and more chronic forms, or in the advanced stages, when it is desirable to promote expectoration or to relieve dyspnoea; and in these circumstances it may be conjoined with orange-flower water, or with hydrocyanic acid, or conium, or the compound tincture of camphor, or with other anodynes, as the peculiarities of the case will suggest.

396. *Salix*, &c.—Besides the barks already mentioned (§ 376, 378), others, especially the

*willow*, the *cedar*, the *larch*, and *fir-barks*, have also been employed in phthisis, but they are useful chiefly as tonics and astringents, and have few other virtues to recommend them. GOURAUD and SCHNEIDER prescribed an extract of the middle bark of the *willow* in this disease; and the *cedar* and *pomegranate* barks were prescribed not merely as tonic in phthisis, but also with the object of destroying intestinal worms, with which this disease was sometimes complicated, especially in low, cold, and damp localities.

397. *Sage* is an old and popular remedy for coughs and colds; it was also much used in pulmonary consumption. It is by no means a bad adjunct to other medicines, and may be advantageously combined with the decoction of *marsh mallows*, in which form it was prescribed by QUARIN and others.

398. *Salts and saline solutions* of various kinds have been prescribed for phthisis, with the intention of moderating the hectic and other symptoms rather than with hopes of curing the disease, although several of them may be as rationally considered capable of effecting this latter object as many other medicines which have been employed with this expectation. Of this class of substances none are more generally useful than the solution of the acetate of ammonia, and of the citrates of the fixed alkalies, of ammonia, and of magnesia. The solution of *acetate of ammonia* is of service chiefly in the early stage of phthisis, and may be prescribed, according to the state of the case, with the nitrate of potash, sweet spirits of nitre, and camphor mixture, with hydrocyanic acid, or with compound camphor mixture, or with conium, henbane, &c. In more advanced or chronic states the ammonia of the acetate may be given in excess, and other medicines substituted for some of those now mentioned. The *citrates of potass*, of *soda*, and of *magnesia* are of service, either individually or with the nitrate of potass and the other substances enumerated, chiefly in advanced stages of the disease, when the blood becomes contaminated by the absorption of morbid materials. In similar states of phthisis the *carbonates of the alkalies* are also of service, especially when given with the *nitrate of potash* or with the *chlorate of potash*, in solution or in vehicles—bitter, tonic, or demulcent—suitable to the requirements of particular cases. The *hydrochlorate of ammonia* was much employed by THILENIUS and MARX in phthisis, as well as in all forms of hectic and in some other fevers, periodic and continued; and was a favourite remedy in these diseases among German physicians early in the present century.

399. *The secale cornutum* has been found very efficacious in arresting the hæmorrhage, in the hæmoptysic states of phthisis. Dr. T—, who had been for many years subject to attacks of hæmoptysis, had recourse, and generally with success, to the secale, in doses of five grains, at intervals of a few minutes, until the discharge began to cease. It was not until at an advanced period of life, and when travelling on the railway, that he was disappointed in the effects of this remedy, for he always carried it on his person. I saw him on his arrival in town, and prescribed oil of turpentine. The hæmorrhage returned some time afterward, and produced suffocation. I had an opportunity of examining the lungs. The appearances are noticed in another place

(§ 91). The hæmorrhage proceeded from ulcerated vessels.

400. *Sulphur* was formerly much employed in phthisis, and was prescribed either in combination with myrrh and various balsams, gum resins, or powders, or in the form of a balsam or electuary, prepared with an essential oil, as the oil of anise seed, or with honey or sirup, and given with such other medicines—demulcent, emollient, anodyne, absorbent, or narcotic—as the state of the case suggested. The anisated balsam of sulphur was especially, and other combinations of this substance, were strongly recommended by ETTMÜLLER, BUSCH, SIMS, AGRICOLA, ROLLO, and others. HUNOLD prescribed it with charcoal in the advanced stage of the disease. The anisated balsam of sulphur, the preparation most frequently used, consisted of one part of the flower of sulphur and four parts of the oil of anise seed, which were digested in a sand-bath. If diarrhœa was present, the sulphur was given with preparations of chalk, or with astringents and tonics. Sulphur has long since fallen into disuse in phthisis; but I have seen much benefit from it in several states of the disease, when judiciously combined and prescribed.

401. *Tartar emetic* was prescribed by SCHLEGEL in small and frequent doses, and was probably employed by him and others on account of the apparent benefit derived from it and other antimonials in the inflammatory complications of the disease. The contra-stimulant doctrine in vogue in Italy at the end of the last century, and in France at the commencement of this, carried the use of tartar emetic in diseases of excited action to an extravagant height; and very probably more injury than advantage was derived from it, owing to its improper use. However, in the more inflammatory, and in the more active hæmorrhagic states of the malady, it is often of service when given either as an emetic, or in frequent small doses, as a contra-stimulant.

402. *Tussilago farfara* has been for ages a popular remedy for chronic coughs and consumptions; and the several parts of the plant have been used in the form of infusion, decoction, electuaries, sirups, &c., for these complaints. It was recommended for phthisis by PERCIVAL, REUSNER, KRAMER, and others; and the mucilaginous, bitter, and mildly tonic virtues of the plant appear to warrant their recommendation.

[The *Black Snake-root* (*Cimicifuga racemosa*) has long been a very popular remedy in consumption in this country, and has been highly recommended by several able practitioners, as Dr. GARDEN, of Virginia (Am. Medical Record, Oct., 1823), and Dr. HILDRETH, of Ohio (Am. Jour. Med. Sci., N. S., iv., 281). It is believed to allay pulmonic irritation like the wild cherry bark, and to exert a sedative influence over the circulation. Dr. HILDRETH recommends employing it in the early stages of the disease, in connexion with *iodine*.]

403. *Turpentine*, in the various modes of its existence, from the essential oil through the terebinthinate balsams to the pine-tops, tar, and tar-water, have been for ages found of benefit in various states of phthisis, some in certain states, and others in other states. These substances, in their several modes of employment, are often of service, not only when exhibited internally, but also when employed externally, and when the much diluted vapour, or even the odour from

them, is inhaled into the lungs. In the hæmoptysic states of phthisis, when it is proper to arrest the hæmorrhage, there is no remedy that is more certainly efficacious than turpentine, when exhibited in small and frequently repeated doses, epithems of the same substance being applied over the chest. It may be taken in doses varying from twenty minims to a drachm every hour, or two or three hours, according to the urgency of the case; or even oftener, either mixed in honey and liquorice powder, as prescribed by GASSER and myself, and as advised in a memoir on the use of this medicine, published in 1820, in the London Medical and Physical Journal; or as directed in a case lately attended by Mr. W. BARNWELL and myself.

No. 363. R Olei Terebinthinæ, ʒiiss.; Spirit. Ætheris Sulphurici Comp., ʒij. Pulv. Tragacanth. Comp., ʒiiss.; Mist. Camphoræ, ʒij.; Syrupi Rosæ et Syrupi Tolutani, aa, ʒjss.; Aquæ destillatæ ad ʒvj. Misce. Fiat mistura, cujus sumatur pars quarta, quartâ quaque hora.

404. The quantity of the oil may be diminished or increased, or the frequency of the dose increased or otherwise, according to the circumstances of the case. There are almost no complications of phthisis which contra-indicate the use of this remedy, when judiciously prescribed, as respects the dose and mode of exhibition; and especially when employed externally also, as hereafter recommended. The terebinthinate substances, in which the essential oil exists in different forms and combinations, are also beneficial when suitably prescribed. The infusion of *pine tops* was praised by CÆLIUS AURELIANUS for phthisis; *tar-water* was recommended by Bishop BERKELEY for this and other diseases; and *tar* was given by SIMS for this malady. I have had recourse to these, especially to tar and tar-water. Tar, in the form of pill, with liquorice powder, is often of great service in the colliquative states of diarrhœa, and when there is reason to fear incipient ulceration of the mucous follicles of the bowels. Tar-water, when sufficiently weak not to be unpleasant to the patient, is also of service in this state of the disease, and in its hæmorrhagic and congestive complications. Indeed there are several states of this malady, and several other diseases, in which both tar and tar-water may be very usefully employed. The injudicious or rather extravagant praises of some writers at the commencement of the last century have caused the complete disuse of an excellent remedy.

405. *Uva ursi*, in powder, decoction, and extract, was recommended for phthisis by Dr. BOURNE, and subsequently by Drs. HAMILTON and DAVY. The tannic and gallic acids it contains, and its astringent and tonic qualities, would justify its use in several states of this disease, especially in the hæmoptysic, and in the colliquative sweats and diarrhœa which occur in the advanced stages. It may, moreover, be combined with other remedies—demulcent, tonic, and anodyne—with opiates, bitters, &c., according to the peculiarities of the case.

[*Alcohol* has recently come into extensive use, not only as a prophylactic, but also as a curative agent in the treatment of tuberculosis. Dr. MARSHALL HALL a few years since extolled very highly the efficacy of alcoholic inhalation, as calculated to check both the deposition and softening of tubercular deposits; one part alcohol to three water is applied, at first tepid, afterward

of the temperature of the air, by means of a few folds of soft linen across the upper part of the chest, the compress to be fastened to the shoulder-straps or other part of the dress, and moistened every few minutes by means of a small sponge. Dr. H. recommends that it be applied every five minutes during the day, so as to secure a constant effect, and he states that it possesses a power in checking the progress of the deposition and softening of tubercle in the lungs beyond any other which he has ever tried. He speaks also of "numbers of patients who have recovered under its use. When taken in this way, as well as through the medium of the stomach, alcohol promotes digestion, retards the metamorphosis of tissue, and sustains the animal heat." As the process of tuberculization, as we have seen, is due to defective hæmatisation and imperfect nutrition, we might, *a priori*, expect that alcohol would prove beneficial. Its prophylactic power, however, we believe to be overrated. The alleged facts on this point need revision. The whole treatment of this disease may be summed up in the aphorism of Dr. RUSH: "The remedies for consumption must be sought for in those exercises and employments which give the greatest vigour to the constitution."]

406. *Venesection* and other modes of vascular depletion, as by cupping or leeches, or by the application of these last to the anus, as insisted on by PLENCIZ and LÄKEREN, with antiphlogistics, emollients, and demulcents, have been advised by many in the early stage of the malady. At this stage venesection, hardly amounting to more than eight or ten ounces at a time, and repeated according to circumstances and to its effects, has been recommended by MORTON, MEAD, PRINGLE, MONRO, FOTHERGILL, SALVADORI, STOLL, HOSACK, FARR, CHEYNE, and others. I have stated above (§ 309-313) the circumstances in which the practice may be adopted; and that it should not always be accompanied with other antiphlogistic remedies, either in an early stage, or when prescribed for inflammatory or hæmorrhagic complications; for depletion, although manifestly indicated, may be followed, in many cases, by suitable tonics and nutrients, provided that exercise be taken with due care in the open air, and that the *external derivation* about to be noticed (§ 415, 416), such as issues or setons, be kept discharging. RUSH advised, for cases requiring venesection, recourse to it in preference, in spring and autumn. But this recommendation is in conformity rather with an old custom than with correct pathological inference. RHODIUS, TRACY, and RUSH considered an attack of hæmorrhage from the nares, rectum, or even from the lungs, beneficial, and the larger the better, and that it should not be too soon arrested, unless manifestly injurious. The opinion is certainly often correct, but the numerous exceptions should not be overlooked.

407. *Various other substances* have been prescribed for phthisis by eminent writers; and, although they may be of little use, farther than as adjuncts to other more beneficial remedies, they may be very briefly enumerated at this place. The *arum triphyllum* was recommended by BURTON, in the form of decoction with milk, the *carduus benedictus*, either in decoction, infusion, or extract with senna, by THILENIUS; the *cryngium campestre*, by HOFFMANN; the *geum urbanum*, by BUCKHAVE, in doses of a scruple and

upward of the powder of the root, as a tonic and astringent; the tops and flowers of *hypericum*, for its balsamic, bitter, and tonic qualities, by LINNÆUS; the *nasturtium aquaticum*, by POUTEAU and BRILLONET; *myrrh*, conjoined with *sulphur*, or various other substances, by numerous writers; the *rhus radicans*, by GIBSON; the *raphanus*, or horse-radish, by SCHENCK and OSIANDER; the *marubium vulgare*, by ALIBERT, a popular remedy, in various forms of preparation, for pectoral complaints in most European countries; the conserve and other preparations of *roses*, by MOSELEY and very many other writers; the *phosphoric acid*, by GORDIN; the *sulphate of iron*, by STRANGER; and *taraxacum*, by SCHMIDTMANN. These hardly require any remark. They may be employed under circumstances which prevent the use of other more beneficial remedies; or in conjunction with such means as have already been advised, as with the Iceland moss, digitalis, conium, &c., or with bitters, as absinthium, calumba, cascarrilla, arnica, &c., when a restorative diet is required, or when indigestion, flatulence, or sinking are experienced. In certain states or complications, as in those just named, the preparations of ammonia, as the carbonate, &c., or the ethers, may be conjoined with other means with benefit. Of the ethereal preparations, the compound spirit of sulphuric ether, the spirits of nitric ether, and the hydrochloric ether are the most useful. In cases where I have prescribed the hydrochloric or nitro hydrochloric acids, with or without the hydrocyanic acid, I have often added the hydrochloric or other ethers when the state of the case required such an addition.

[In this connexion the *wild-cherry bark* deserves favourable mention, for its admirable combination of sedative and tonic properties. The cold infusion of the inner bark of *Cerasus Scrotina* has long had a high reputation in this country, in cases of general debility, with feeble digestion, and frequent pulse, and especially in pulmonary tuberculosis. It rarely fails to lessen the frequency and increase the force of the pulse, while it invigorates all the functions. "Few remedies," says Prof. WOOD, "are better adapted to hectic fever, from whatever source it may proceed." The best preparation is the cold infusion, made with half an ounce of the bark to a pint of water, prepared by percolation, and given in doses of two ounces three or four times a day. It may be used to great advantage in connexion with cod-liver oil.]

408. xiii. MINERAL WATERS have been recommended by several authors; but they require much caution and consideration before entering upon the use of any of them, when the disease has fully declared itself. In the scrofulous diathesis, and when the disease is threatened, or when its prevention should be attempted, these mineral waters are often of great benefit, when taken in proper quantity, and in suitable dilution, in certain cases. The quantity of these waters usually recommended is often not duly regulated, or suited to the nature of the case and to the effects produced; and hence they are either inefficacious or injurious. There are three kinds of mineral waters, which, when used in proper quantity and combination, and their effects watched, are sometimes beneficial both in the prevention and in the treatment of the early stages of phthisis; these are the *chalybeate*, the *sulphureous*, and the *alkaline*; each, however,

being suited only to certain states or forms of the disease. It should not, however, be overlooked that all these waters contain various proportions of different saline ingredients—the oxides or salts of iron, or sulphureted hydrogen, or alkaline carbonates, being present in certain of these waters also in various proportions.

409. *a.* The *chalybeate mineral waters* are chiefly indicated in those states of the disease for which the compound iron mixture has been recommended above (§ 378), more especially in lymphatic and phlegmatic temperaments, and when the pulse is weak, small, or slow, and the blood poor in red globules. Generally the weaker chalybeates, or the stronger more or less diluted, are most beneficial, and should be preferred for cases where their use is of doubtful propriety. The mineral waters of *Aix-la-Chapelle*, especially the sulphureted chalybeate, have been recommended for this class of cases; but the mineral waters of this country, of a similar composition, are equally appropriate with those, especially the chalybeate and saline spring at *Harrowgate*, which may be taken alternately with the sulphureous waters of that place. The mineral waters of *Kissingen* are also of service early in the disease, or when phthisis is threatened, especially when the several springs are employed under judicious medical direction.

410. *b.* *Sulphureous mineral waters* are often beneficial in phthisis, especially if the composition of the several springs containing sulphureted hydrogen gas be such as may be appropriately employed for individual cases. The several springs at *Harrowgate* supply a sufficient variety of composition to suit the various states of different cases. The waters of *Moffat* and *Strathpeffer* are stronger in sulphur than those of *Harrowgate*, but they present a less variety of composition. The waters of *Enguien* and *Barèges* may also be tried, but they offer even fewer advantages than those already mentioned.

[There are several mineral springs in the United States whose waters are reputed beneficial in phthisis pulmonalis, especially the chalybeate waters of *Saratoga*, and the sulphur and saline springs of *Virginia*, particularly the *Red Sulphur*. The latter, containing *carb. acid*, *nitrogen*, *oxygen*, *hydro-sulphuric acid*, *sulphate soda*, *carb. lime*, *carb. magnesia*, *sulphur compound*, &c., have the property of reducing the frequency of pulse and tranquillizing pulmonic irritation in a very remarkable degree. It is not uncommon for a hectic pulse of 120 to be reduced to the natural standard in the course of a few days under the use of the waters, while at the same time the appetite is increased, the night-sweats checked, and the general system invigorated. The medicinal virtues of these waters, together with the delicious climate in summer and autumn, the romantic scenery, and the accommodations and comforts afforded to the guests, render the *Virginia Springs* a pleasant and profitable resort to the invalid. The sulphur springs of *Richfield*, *Sharon*, and *Avon* also deserve favourable mention in this connexion.]

411. *c.* The mineral springs abounding in the *carbonates of the alkalis*, as well as holding various other substances in solution, have likewise been recommended for threatened and incipient phthisis. The chief of these are the waters of *Ems*, *Seltzer*, and *Vichi*. These are usually most beneficial when taken with milk or with whey.

The *Ems* waters are much praised by *BRUCHMAN* and others, and the *Seltzer* by *BANG* and *KRAMER*, in this disease, especially when diluted with milk or whey. The waters of *Cauterets* have also been recommended by many; and those of *Bonnes* and *St. Saurcur* of the *Pyrenees* have proved most beneficial in several instances which have come before me. Whatever mineral water be adopted, other means, medicinal, regimènal, and dietetic, are generally also required. Some advantage, moreover, is derived by consumptive invalids from change of scene and of modes of living, and from dryness of the air and elevation above the level of the sea, when they visit some of the inland or continental watering-places. Increased exercise in the open air, and in open day and sunshine, is also not devoid of some benefit.

412. *xiv.* *INHALATION* of various fumes and vapours, chiefly medicated in various ways, and by diverse means, has been advised by many.—*a.* I have seen several modes of inhalation employed, and have prescribed certain of them, but without any very manifest benefit. The great disadvantage of most of these means is occasioned either by the amount of aqueous vapour thus passed into the lungs, or by the irritating or other effects produced in the air-passages by the ingredients employed. I have already noticed the subject of inhalation above (§ 324), and when treating of *bronchitis* (see art. *BRONCHII*, § 98, *et seq.*); and the opinion I have stated under this latter head a farther experience has fully confirmed. I may mention, however, that the inhalation of sulphuric ether, with the vapour from preparations of conium, was advised by *Dr PEARSON*; of vapour containing the fumes of *Burgundy pitch*, by *HOMÈ*; of aqueous exhalations from *henbane*, *myrrh*, and “*naphtha vitrioli*” (sulphuric ether), by *JOERDENS*; of the fumes from *pine-tops*, and various balsams, by a number of writers; and of tar-vapour, by *CRICHTON* and *PAGENSTECKER*. But the usual modes of inhalation, especially those in which inhalers are employed, are most objectionable, and much more injurious than beneficial.

[After much experience in the use of inhalation in phthisis, we fully agree with our author that, in general, it is, as practised, more injurious than beneficial. We have tried a great variety of substances, as *iodine*, *chlorine*, *creasote*, *tar*, *bals. Tolu* and *Perru*, *styrax*, *benzoïn*, *copaiba*, *turpentine*, &c., and we cannot say that we have ever seen any essential, permanent benefit from their use in tubercular phthisis. In bronchial disease they often prove useful by their local alterative action, and doubtless in many such instances exert a curative influence. As consumption is generally connected with bronchial irritation and inflammation, medicated inhalation often proves a useful palliative, allaying irritation, and affording some relief to the cough. Hence the popular belief in its efficacy in such cases. But in a constitutional affection like tuberculosis, the local application of medicines to the bronchial tubes, whether by inhalation or any other method, can only be expected to palliate, never to cure, the disease. Patients are often flattered into a belief that they are rapidly improving under this process, while all that is effected is a slight diminution of the most harassing symptom, viz., the cough. This mode of practice is now chiefly resigned to the hands of noted quacks and empirics, where it properly belongs.]

The late *Dr. MORTON*, of *Philadelphia*, em-

ployed inhalations to a considerable extent in every stage of phthisis, and, as he believed, with beneficial effects. In some cases he combined conium with iodine, after the manner of Sir CHARLES SCUDAMORE, as follows :

R Iodini puri, Iodidi Potassii, āā, gr. vj.; Aquæ distillatæ, ℥v.—℥vj.; Alcoholis, ℥j. Fiat mistura.

From 3ss. to 3j. of the saturated tincture of conium is added, with the same quantity of the iodine mixture, to the water in the inhaler of 120°, at each inhalation of 8 to 10 minutes' duration, increasing the quantity of each according to circumstances. We have tried this combination in several cases of phthisis with apparent temporary benefit. Instead of the above, Dr. MORTON came at last to prefer the following preparation :

R Iodini puri, gr. iv.; Foliorum Conii, gr. viij.; Etheris Sulphurici, ℥j.

Digest for 48 hours; add a teaspoonful to a wine-glass of warm or tepid water; hold in the hand, and inhale the vapour as it rises. In 10 to 15 minutes the evaporation is complete. If it causes cough or dizziness, use a smaller quantity, or hold it farther from the nostrils. Dr. MORTON preferred this method to the inhaler. The most that inhalation, however, can do, in any case, is to palliate some of the symptoms.]

413. *b. Weak fumigations* diffused through the apartment occupied by the patient are much more beneficial than any mode of inhalation; and the vapour, or the weak fumes, or rather the odours, exhaled from the substances employed for the purpose of impregnating the air of the apartment, are sufficiently strong to be respired by the patient in most cases. The greatly-diluted fumes or vapours proceeding from creasote, from tar, from turpentine or the several terebinthines, from pine-tops, from various balsams, from the ethers, especially pyroligneous ether or pyroxalic spirit, from cedar, and from resins, gums, &c., independently of any combination with aqueous or narcotic vapours, are generally much more beneficial and pleasant to the patient than the inhalations commonly employed. The embrocations so frequently recommended for this (§ 321, 322, 403) and several other diseases act beneficially, chiefly in consequence of the inhalation by the patient of the ingredients as they are evaporated, or as their dilute fumes are exhaled and diffused in the air surrounding him. A young man, who had repeatedly come under my observation in an advanced stage of phthisis, completely recovered his health after he had been for a considerable period employed in the manufacture of creasote. When the cough is distressing, the fumes of ether, arising from the sprinkling of one or other of these, especially of the spiritus ætheris sulph. comp., the pyroligneous ether or pyroxalic spirit, or the hydrochloric ether, or of chloroform, on the bed-clothes of the patient or on any article more or less removed from him, will often have a very palliative effect.

414. XV. THE EXTERNAL MEANS of treating phthisis have been already partly noticed (§ 319, 323). —A. Among these, *medicated and mineral baths* have been advised by several writers, more especially the warm mineral springs of the continent. Sulphureted chalybeate baths were recommended by LENTIN; the baths of *Baden* were praised by SCHENCK, and those of *Weisbaden* by RITTER, especially for the early stages of phthisis; but they are more likely to be of service for the pre-

vention of the disease, aided by more beneficial means; for very little dependence can be placed upon thermal springs or baths, either in the prevention or cure of this malady. Whatever benefit is derived in some cases is to be imputed as much to change of air, exercise, and regimen as to the effects of the baths.

415. *B. External derivatives and exutories* have been advised for phthisis from the earliest periods of medical history. I have stated above (§ 319–323) the modes in which these may be employed, and the general results of my experience of them. I shall only notice the opinions of a few writers respecting them: the views of many eminent authorities on this important department of medical practice may be gathered from the historical sketch I have given above (§ 242–287). During the course of my medical experience I have not observed this practice employed in the manner in which it is most efficacious. Tartar-emetic ointments, croton-oil liniments, &c., have been frequently resorted to in recent times; but issues and setons have been rarely employed, although the experience of numerous writers, as well as my own experience in several cases, has demonstrated their great utility. The selection of a situation in which an issue may be made or a seton inserted is often the chief difficulty in the way of either. BARTHOLIN directed an issue to be made in the back, below the scapulæ; DUPLAN and RIVIERUS between the scapulæ; GEBEL, DREYSIG, and BILLARD, in the upper arm; SIMMONS recommended a seton to be inserted in the nape of the neck; MONRO, PORTAL, and HILDENBRAND, in the arm; ZACUTUS LUSITANUS, at the edge of the pectoral muscle, near the axilla; WHYTT and RUSH preferred the same situation for a seton, or near the sternum for an issue, LENTIN also selecting these places in preference to others. While these and many other authors have thus resorted to these means in phthisis, they have not considered them suitable to all states or stages of the malady. QUARIN, WINTINGHAM, and SOUVILLE, who have been less in favour of these means than the writers just referred to, consider them worse than useless in the far-advanced course of the disease, and when there is much exhaustion. Having often employed them with advantage—in some instances in the families of medical men of my acquaintance—I am enabled to state that I have generally preferred issues, kept discharging by means of a number of peas, to setons; that, when the patient is not much emaciated, some part of the breast, or over the margins of the false ribs, has been preferred; that this practice is of service chiefly in early stages, before cavities are formed, and in the more usual and chronic forms of the disease; that it is more especially beneficial in the hæmoptysic and congestive complications; and that it should not be resorted to in the more febrile, debilitated, and emaciated cases, and when the signs of cavities are manifest. It ought to be farther recollected that time is a necessary element in the development of the effects of this treatment; that the other means of cure, the diet and the regimen adopted, should be restorative and nutritive, without being heating or stimulating, especially as the discharge from the issue or seton becomes copious; and that air and exercise in the open day, avoiding injurious exposure, should not be neglected.

416. *C. Blisters, rubefacients, and embrocations*

(§ 319-323) have been sufficiently noticed. The first of these, when kept discharging for some time or frequently renewed, is often of service, and may be substituted for issues or setons when these latter will not be adopted by the patient. The *embrocations* which I have so often mentioned are of service, both as irritants or rubefacients, and as furnishing the best means of inhalation. *Cauteries*, actual or potential, formerly employed and recommended by HIPPOCRATES, GALEN, and others of the ancients, and by PORTAL, AULAGNIER, GARDOUIN, &c., among the moderns, are rarely prescribed; and even *moxas*, although much praised by LARREY and other recent writers, are seldom resorted to. *Urtication*, which was recommended by LANGE, is also superseded by other means. That pustular eruptions and purulent discharges artificially produced have more or less influence in delaying or arresting the progress of phthisis, when the disease is not far advanced, is among the most important facts in medical practice; but much more is required than an empirical recourse to such means. A knowledge of the cases, states, and stages of the malady in which they are likely to be of service, or at least not to be detrimental, and of the other means, constitutional, local, external, and regiminal, which may be brought to their aid, is essential to success in the employment of them. That the production of a purulent discharge or the formation of a purulent eruption has sometimes cured phthisis, appears to have been known from the earliest periods of medical history. After the appearance of small-pox, it was observed that a copious eruption in that malady often cured pulmonary consumption in an early stage, and as often accelerated the progress of this latter disease in an advanced stage. This was remarked by MÜYNIK, BRACHET, and others; and it has been stated by writers that phthisis is rarely observed in persons much marked with small-pox (§ 231)—a statement which has appeared to be confirmed by my own observation.

417. xvi. STATES OF THE AIR were much discussed by writers from the middle of the last century until early in this, in respect of consumption, and all sorts of air were considered with reference to the cure of this disease. The air of cow-houses was advocated by some, of marshes by others (§ 295). Even the mephitic air produced by bilge-water (arising chiefly from the action of salt-water upon the ship's timbers) was considered by BEDDOES and HARRISON as the cause of the benefit derived from voyaging. The use of fixed air, soon after its discovery, in the treatment of phthisis, was most unprofitably discussed by writers from 1780 to the commencement of this century; and although the influence of the carbureted and sulphureted hydrogen, and other gases given off from bilge-water, may be considered by some as disposed of, yet it is still viewed as not without some favourable influence by those who believe in the good effects of marshy exhalations in threatened phthisis.

[Dr. S. G. MORTON, in his "Illustrations of Pulmonary Consumption," first published in 1833, suggested (p. 261) that, as the only equable climate of the United States is that of the Mammoth Cave of Kentucky (its temperature differing but little the year round from 56°, and perfectly dry), it might at some future period become a place of hibernation for invalids, "where they will be shielded alike from the cold, the wet, and the

noise of the world above them." This hint was taken advantage of by its proprietor soon after, and several huts were erected a mile or more from the entrance of the cavern, which were inhabited throughout the winter months by consumptives from different parts of the United States. The first effect of the under-ground residence in a few cases appeared decidedly favourable; the cough was arrested in a great degree, and a quiet, placid feeling pervaded the system. The absence, however, of light, the want of exercise, the monotony of life, the smoke from fires and lights, &c., rendered existence under such circumstances intolerable, and, on emerging again to the light of day, the disease progressed with astonishing rapidity to a fatal termination. Altogether, twelve different patients tried the experiment of living within the cave from one to six months each, but in no instance with any permanent benefit.—See 31st vol. *Boston Medical and Surgical Journal*, June, 1844.]

418. That fixed air contained in fluids is a useful palliative in this disease, and for the dyspeptic symptoms which accompany, cannot be doubted; and that the sulphureted hydrogen contained in some mineral waters is often beneficial, as most preparations of sulphur are also more or less so, in tubercular states of the lungs, must be admitted, as far as medical observation and experience warrant the belief. But this refers only to the gases impregnating fluids taken into the stomach.\*

419. Of much greater importance is the determination of the questions, whether or no the air in very elevated situations, or in low places, and whether that near the sea, or at a distance from it, is the most beneficial to phthisical cases? Or, in other words—1st. What is the state or states of the air which the phthisical patient may breathe with greatest benefit? 2d. Should the states of the air, found beneficial in certain seasons, be continued in other seasons? and, 3d. If change of such an air be found requisite, how should it be most appropriately and beneficially changed with the procession of the seasons?

420. 1st. *Sea voyages* were praised by CÆLUSUS, ARÆTEUS, and others among the ancients; and by GRANT, SAVARY (*Lettres sur l'Égypte*, t. iii., p. 8), and many among the moderns. But it is very doubtful what share of the benefit observed proceeds from the sea air itself, or from the motions and other circumstances connected with the voyage. It is not improbable that the sea air may contain certain elements beneficial to morbid states of the lungs, and sufficient to counteract any injurious influence which humidity alone might produce. But persons living on the seacoast are not much more exempt from phthisis than those living inland, where equally humid states of air, within the same ranges of temperature, usually exist. A greater exemption may be experienced, but the amount has not yet been ascertained, or even an approximation to it. The ancients inferred benefit from sea air, because the

[\* If we bear in mind that the principal indication in phthisis is to improve the faulty nutrition, which is the cause of the tubercular exudation, and invigorate the general system, we shall avoid the use of such drugs as tend to impair the tone of the digestive organs, and we shall find, moreover, that as the digestive powers and the general health are strengthened by suitable hygienic means, the local as well as general symptoms will yield, and there will be little occasion for those special remedies for sweats, cough, diarrhoea, &c., which have hitherto been in such general use.]

voyages for the cure of pulmonary diseases were generally made to Egypt, and very probably the relief manifested soon after the arrival of patients in that country was partly at least attributed to the voyage. Although Dr. SMYTH is not in favour of sea air for consumptive cases, yet I know that voyaging in the Mediterranean and in the Atlantic has been most beneficial in several cases in which I have advised it. But I agree with CÆLIUS AURELIANUS, GILCHRIST, BLANE, REID, and many others, in saying that, in order to be of service, it should be adopted early in the disease; if it be resorted to at a far-advanced period, and if a very warm latitude be entered into, the disease will most probably be accelerated to a fatal issue. The doubt expressed by me above (§ 307) of the superiority of the sea-coast to inland situations, other circumstances being equal, appears to be confirmed by the observations of Dr. RICHARDSON respecting the climate of Nubia, of Dr. BARCLAY on the climate of Egypt, and of Dr. ARCHIBALD SMITH on the influence of high elevation in warm climates on consumption. In *Nubia, Egypt*, the South of *Spain*, and at a considerable elevation on the *Andes*, cases of this disease, whether attended by hæmoptysis or not, were remarkably benefited soon after their arrival; and a removal from the last-named place to the sea-coast was often followed by a return of the malady. From the testimony and experience of these eminent writers, and from what other sources of information have furnished, I infer that dry states of the atmosphere, in moderate grades and ranges of temperature, and at considerable or even moderate elevations above the sea-level, are most favourable to consumptive patients; that the places just named, and Malaga, and various other places in Syria and the East, are most to be preferred; and that, before the commencement of the hot season, Nubia, Egypt, and other places, where the temperature rises very high, should be relinquished for others which are more temperate.

[*Climate in Tubercular Phthisis.*—With regard to the influence of the climate of different regions of the United States in the causation of tubercular phthisis, the positive facts bearing on the subject are not yet sufficiently numerous to enable us to draw any very positive conclusions. The late Dr. SAMUEL FORRY, in his able work on "The Climate of the United States and its Endemic Influences" (based chiefly on the records of the Medical Department and Adjutant-general's Office, United States Army), having first established the *isothermal* and *isochermal* lines, representing the mean temperature of summer and winter (from which it appears that the same parallels of latitude present systems of climate very diverse in character, as, 1st. The regions bordering on the ocean; 2d. Those under the influence of inland seas; and, 3d. Those remote from such controlling powers), demonstrates very clearly that these laws of climate maintain an intimate relation with the etiology of pulmonic diseases, and that the prevalence of *catarrh* and *influenza* in each system of climate increases and decreases in proportion as the seasons are contrasted, thus maintaining an unvarying relation with the extreme range of the thermometer as connected with the seasons.

The following table from his work, exhibiting the ratio of cases per 1000 of mean strength, will show the comparative prevalence of pulmonary diseases in each system of climate:

NORTHERN REGION OF THE UNITED STATES.	Mean Strength.	Catarrh and Influenza.	Pneumonia.	Pleuritis.	Phthisis Pulmonalis.	Total.
Atlantic Ports .....	3,130	233	22	26	9	290
Posts on the Lakes .....	5,975	500	19	30	9	538
Posts remote from the ocean and the Lakes. }	12,604	552	17	28	5	602
Total.....	21,707	439	18	28	7	490
SOUTHERN REGION.						
Coast from Delaware to Savannah .....	3,799	271	25	32	13	341
Southwestern Stations .....	11,140	290	39	52	11	392
Posts on the Lower Mississippi. ....	3,381	218	22	28	9	277
East Florida.....	4,607	143	15	24	9	191
Total.....	22,327	246	29	49	11	236

If these statistics are reliable, the annual ratio of pulmonary diseases, with the exception of catarrh and influenza, is lower in the northern than in the southern regions of the United States; pneumonia, pleuritis, and phthisis pulmonalis are most prevalent, however, in the middle regions of the United States, and Florida has a lower average than any other. The ratio of deaths per 1000 of mean strength is, in the northern region, 2.1, southern 4.4, from phthisis; and in the former 0.5, the latter 1.8, from pneumonia, pleuritis, and catarrh. This corresponds with the conclusions deduced from the "Statistical Reports on the Sickness, Mortality, and Invaliding" among the British troops stationed in every part of the globe. The reporter shows by numerical results that phthisis pulmonalis is more prevalent in southern than northern latitudes, and infers "that it is by no means likely that any beneficial influence can be exerted by climate itself in pulmonary affections."

These facts also correspond with what has been observed in Europe. Phthisis is far more prevalent in the middle and southern regions of Europe than it is farther to the north; while in Sweden the ratio of deaths from this disease is only 63 in 1000, in London it is 236. The northern parts of Russia are comparatively exempt from the disease, while from the 35th to the 45th parallel of latitude it is very common.

The popular notion that a changeable climate favours the production of phthisis is undoubtedly erroneous. Those who are most exposed to the vicissitudes of climate are least exposed to pulmonary disease of every kind. Statistics have fully proved that the maximum of liability to phthisis is found among those who suffer the least exposure to climatic variations; and it will even be found true that the most variable climates are best calculated to develop the physical and mental powers. Doubtless, it is owing to this cause that the Indians, our frontier inhabitants, and the hardy backwoodsmen of the West, are so little liable to attacks of phthisis. The above holds true also, according to Dr. FORRY, in regard to pleuritis, pneumonia, and catarrhal affections, which, he says, are far less prevalent in the moist and changeable climate peculiar to the Atlantic coast and the borders of our great lakes than in the dry atmosphere of the interior parts of the continent. The above facts are also corroborated by the recent "Statistical Report on the Sickness and Mortality in the Army of the United States, compiled from the Records in the Surgeon-General's Office," for sixteen years (Washington, 1856, 4to). For example, Surgeon WOTHERSPOON, in giving an account of the "Medical Topography and Diseases of Fort Kent" (lat. 47° 15' N., long.

68° 38' W.), remarks that "the climate of Fort Kent does not seem favourable for the production of pulmonary phthisis. During my sojourn at the post, I have neither seen nor heard of a case of this disease among the French or American settlers. Assistant-Surgeon ISAACS, who, during the two years he was resident at the fort, had a much better opportunity than myself of becoming acquainted with the diseases of the country, informs me, not only that he never saw a case of consumption in the country, but that some of the inmates of the garrison, who were affected with suspicious symptoms, recovered from them entirely" (p. 27).

From this recent "Report" we copy the following "Consolidated Table," exhibiting the amount and ratio of sickness and mortality in the several regions from phthisis pulmonalis:\*

Regions.	Mean strength.	Number treated.	Deaths.	Ratio of Cases per 1000 of mean strength.
Coast of New England ..	3,963	19	5	4.8
Harbour of New York ..	9,387	56	35	5.9
West Point .....	6,901	6	8	0.8
North Interior, east....	3,553	17	10	4.7
The Great Lakes.....	10,346	47	33	4.5
North Interior, west....	7,330	30	15	4.1
Middle Atlantic.....	6,249	16	19	2.5
Middle Interior, east...	2,456	6	3	2.4
Newport Barracks, } Kentucky.....	1,454	5	4	3.4
Jefferson Barracks and St. Louis Arsenal....	5,580	23	21	4.1
Middle Interior, west....	5,319	28	13	5.2
South Atlantic.....	2,800	26	5	9.2
South Interior, east....	5,919	43	23	7.2
South Interior, west....	10,013	20	25	2.
Atlantic Coast of Florida	835	2	1	2.3
Gulf Coast of Florida ..	2,299	16	3	6.9
Texas, southern frontier	4,450	13	11	4.
Texas, western frontier.	6,324	25	12	3.9
New Mexico .....	5,873	8	3	1.3
California, Southern....	1,707	9	5	5.2
California, Northern....	1,599	9	4	5.6
Oregon and Washington	1,831	6	2	3.2

From this table we gather that the lowest ratio of cases of consumption occurs in New Mexico, being only 1.3 per 1000, and the highest in the South Atlantic region, where it is 9.2 per 1000. Assistant-Surgeon HAMMOND observes that he had never seen but two cases of the disease in the country (New Mexico), and those came from the United States. The south interior, east, and Gulf coast of Florida give the next highest proportions, being respectively 7.2 and 6.9 per 1000 of mean strength. The ratio for these three regions, and also for California, are higher than for any of the regions in the United States. The compiler of this work, Dr. COOLIDGE, arrives at the following conclusions in regard to climatic influences in the production of this disease:

"1st. That temperature, considered by itself, does not exert that marked controlling influence upon the development or progress of phthisis which has been attributed to it.

"2d. That the most important atmospherical condition for a consumptive is *dryness*.

"3d. That next to *dryness* in importance is an *equable* temperature—a temperature uniform for long periods, and not disturbed by sudden or frequent changes. A uniformly *low* temperature is

much to be preferred to a uniformly *high* temperature. The former exerts a tonic and stimulating effect upon the general system, while the latter produces general debility and nervous exhaustion. The worst possible climate for a consumptive is one with long-continued high temperature, and a high dew-point." The British Army Statistical Reports confirm the truth of these statements, the ratio of cases of phthisis among the troops in Canada being 5.7 per 1000 of mean strength, while in Bermuda it is as high as 8.9.

Such being the facts in regard to climatic influences in the production of tuberculosis, the important question recurs, are consumptive patients to be sent away from home; and if so, whither shall they be sent? English physicians have from time immemorial been in the habit of sending their pulmonic cases to Rome, Naples, Nice, Florence, and other parts of Southern Italy, Montpellier, Lisbon, &c., places particularly subject to bronchial and tubercular affections, and where a greater proportion of the native inhabitants perish from this class of diseases than in any part of Great Britain. Even in Madeira, so vaunted as salubrious in tuberculous cases, consumption and scrofula are very common diseases, and the average duration of life is inferior to that of our own country. Indeed, all known facts seem to prove that the notions which have hitherto prevailed in regard to the beneficial effects of change of climate in this disease are utterly unsound and fallacious. As Dr. BURGESS\* has well remarked, "We may seek in vain along the entire range of organized existence for an example of diseased animals being benefited by removal from a warm to a cold, or from a cold to a warm country. There appears nothing in the Book of Nature so violently inconsistent. The fishes which inhabit the waters of the British islands will not thrive in the Arctic seas, nor those of the latter in the ocean of the tropics; our birds generally die when carried to Europe, and the wild animals of Africa and Asia perish when translated to our own continent. Man, it is true, is a cosmopolite, and can bear sudden changes and unnatural transitions better than any other animal; still, his constitution and health are endangered by such opposite conditions, as we see among the blacks removed from the South to Canada, and among the inhabitants of northern latitudes who remove to the tropics, and *vice versa*. Well may it be asked, if such extreme changes of climate prove obnoxious to the health of individuals having naturally a sound constitution, how are we to expect persons in a state of organic disease to be thereby benefited? Nature has, in fact, adapted the constitution of man to the climate of his ancestors, and that is the natural climate of man in which not only he himself was born, but also his blood relations for several generations. This is his natural climate, as well in health as when his constitution is broken down by positive disease, or unhinged by long-continued neglect of the common rules of hygiene." We believe, therefore, with BURGESS, that *change of air in his own climate*, or removal to one nearly approaching to it, is the natural indication, and will effect whatever good climate can effect in consumption.

When tubercular disease, then, is fully established, a residence at home, if in a favourable sit-

\* The northern division includes that portion of the United States north of the 40th degree of latitude and east of Rocky Mountains; middle division lying between 35th and 40th parallels of latitude; southern division between 30th and 35th degrees of latitude. Besides these are the divisions of Florida, Texas, New Mexico, California, Oregon, and Washington Territories.]

[\* "Climate of Italy, in Relation to Pulmonary Consumption." London, 1852.]

uation, with all the comforts and consolations of home, is far preferable to any of the remote resorts recommended in such cases. We have seen that more cases of phthisis originate in warm than in cold climates, and are also more speedily fatal; and it would be easy to show that while cold retards the progress of the disease, heat accelerates it. Tubercular softening, as we have had many opportunities of observing, is much hastened by warmth and moisture, as in removing from New England to Cuba, or any of the West India islands. We admit, however, that there are exceptional cases, where consumptive persons seem relieved as soon as they reach a warmer and more uniform climate. But these are either cases of pure bronchial disease, or *broncho-tubercular*, where a warm, moist air allays the irritability of the bronchial mucous membrane, and affords great relief to the cough and the general sensations of the patient. It is a mistake, however, to suppose that rapid variations and an extensive range of temperature are unknown to warm climates. Such variations are very great and frequent in Southern Italy, and along the Atlantic coast of Florida and our Southern States.

If, however, it is thought desirable, for the patient or physician, that a change of climate should be made, there is no necessity that he should be sent abroad while we have every possible variety of climate in our own country. *Change of air in the same climate* is what should be sought, and not a climate greatly foreign to that of his own. An *equable* temperature is what is required, and every consumptive patient who has tried a change of climate will testify that a low degree of temperature, with a limited range, gives more permanent ease than a high degree subject to frequent alternations. Such a winter climate is found in many parts of the United States. We have little doubt the time is not remote when, instead of sending tuberculous cases to spend the winter at the South, southern invalids will seek the bracing atmosphere of the North, and return home in the spring greatly invigorated. The above remarks, I am aware, are in opposition to the maxim of CELSUS, that "the air in which a man grows sick is the very worst air for him;" and also in opposition to the opinions of many enlightened physicians, like Professor DICKSON, who thinks a change of climate in such cases "is always desirable;"\* and that "a northern winter should be avoided by migrating to a southern latitude; and that a southern summer is almost equally dangerous in its ultimate effects," &c. Dr. RUSN advised American patients to pass the winter and a part of the spring in South Carolina and Georgia; in summer to go northwardly into Canada as far as Quebec, and to return in autumn to Pennsylvania and New Jersey.† He inculcates strongly the necessity of keeping far from the sea-coast, believing a mixture of sea and land air highly prejudicial. Dr. DICKSON remarks that "the atmosphere of islands, of many points on the coast, Madeira, the West Indies, St. Augus-

tine, and Savannah, is found to be generally salubrious to pulmonary patients."—*Loc. cit.* Of the numerous patients we have sent to these different places with confirmed phthisis, we can scarcely call to mind a single case which was essentially benefited, while in numerous instances the patients became suddenly worse. Great relaxation and debility ensued, with an increase of the night sweats, hæmoptysis, and diarrhœa, if present; the high temperature rendered exercise in the open air next to impossible, while there was a general absence of those comforts and appliances procurable at home. The appetite usually fails on transference to a tropical clime, and tubercular softening makes rapid progress.

Admitting that the ratio of pulmonary diseases is as high, or higher, in southern than in northern latitudes, we grant it does not necessarily follow that benefit may not be derived from change of climate in the way of a *winter* residence. This must be decided by actual experience only, and experience we hold to be generally adverse to the doctrine. The late Dr. FERRY, who was personally acquainted with the climate of Cuba, Florida, and our Southern States, was in the habit of recommending a residence in those localities during the winter months, in cases of bronchial disease and incipient or threatened phthisis, or "when mostly limited and merely nascent," but never after the latter disease was unequivocally established. Sir JAMES CLARK also remarks that "the climate of the West Indies is an improper one for patients with tuberculous disease of the lungs."—"On Climate."

The idea is a prevalent one in the profession, that residence in a malarious district acts as a prophylactic against tubercular phthisis; but the evidence on this point is very conflicting. It is

[\* Essays on Pathology and Therapeutics, p. 317, vol. ii. (1845).]

† It is a common belief that there has been a gradual change in the temperature of our summer and winter months during the last 50 years, our summers growing hotter and our winters colder during that period. An examination of the following tables, for which we are indebted to the kindness of Professor PARKER CLEVELAND, LL.D., will show that there has been no essential change in these respects during that period:

doubted whether malaria exerts any antidotal or curative power in regard to tuberculous affections. On the contrary, it is stated on good authority that malaria powerfully predisposes to such attacks, and that a malarial fever frequently lays the foundation for tubercular disease. Nothing, indeed, is more common than to witness the superposition of rapid pulmonary consumption in constitutions deteriorated by malarial diseases. "An attack of ague," says Sir JAMES CLARK, "is much more likely to favour the occurrence of consumption than to prevent it."—"On Climate." "Whenever any cause," says Dr. FORRY, "depresses the vital energy, and lowers the power of assimilation beyond a certain point, the tubercular diathesis will be produced. Moreover, the connexion of pulmonary phthisis with congestion and derangement of the abdominal viscera has been long since noticed; and as abdominal plethora is the predominant character of the prevailing diseases of tropical latitudes, we have a ready explanation of the high ratio of tubercular consumption in the West Indies. Hence malaria has a tendency to develop this disease, for it tends to destroy the balance of the functions and diminish the tone of the system, thus robbing the blood of that rich, fibrinous, and vital condition, by which proper nutrition and the organic functions are sustained. Malaria holds a prominent place among the causes productive of the cachectic condition of the system which precedes the formation of tubercle."—*Loc. cit.*, p. 266.

The opinion generally prevails that a mixture of sea and land air, such as exists on all our maritime situations, is unfavourable to delicate lungs, especially where there is phthisis, or a strong predisposition to it. Such was the opinion of the late Dr. S. G. MORTON, Sir JAMES CLARK, and perhaps a majority of writers on this disease. Such also is the result of our own observation. But it conflicts with the statements of Dr. FORRY, and other statistical writers, that pulmonary diseases are scarcely half as prevalent on the moist and variable coast of New England, as well as the Lakes, as in the dry and less changeable regions of the same latitude. We regard this question, however, as far from being settled. The laws and conditions regarding the causation of tubercular disease are probably far from being the same as those connected with inflammatory affections of the lungs. LAENNEC has remarked that few consumptive cases occur near the sea; the comparative ratio, however, may vary in different countries in the same latitude, and also at different latitudes. In Georgia and Florida the opinion prevails that the dry air of the interior, in conjunction with the aroma of pine forests, is more congenial to delicate lungs than the moist air on the coast. The ancients sent their consumptives to the pine-forests of Egypt. CLOT BEY, in his recent work, states that Egypt enjoys an exemption from lung diseases, especially from phthisis, and he therefore recommends it as a residence for persons predisposed to or labouring under this disease. Such pulmonary invalids as seek a milder winter climate may be safely recommended to the pine regions of the interior of South Carolina, Georgia, or Florida, where all the advantages of a change of climate may be found which are to be expected in such cases.

Mr. A. KEITH JOHNSTON ("The Physical Atlas of Natural Phenomena," ed. 1856) observes, as regards consumption, as follows: "It originates

in all latitudes—from the equator, where the mean temperature is 80°, with slight variations, to the higher portion of the temperate zone, where the mean temperature is 40°, with sudden and violent changes. The opinion long entertained that it is peculiar to cold and humid climates is founded in error. Far from this being the case, the tables of mortality of the army and navy of this and other countries, as well as those of the civil population, warrant the conclusion that consumption is more prevalent in tropical than in temperate countries. Consumption is rare in the Arctic regions, in Siberia, Iceland, the Faroe Islands, the Orkneys, Shetlands, and Hebrides. And, in confirmation of the opinion that it decreases with the decrease of temperature, FUCHS shows, from extensive data, that in Northern Europe it is most prevalent at the level of the sea, and that it decreases with increase of elevation to a certain point. At Marseilles, on the sea-board, the mortality from this cause is 25 per cent.; at Oldenburg, 80 feet above the sea, it is 30 per cent.; at Hamburg, 48 feet above the sea, it is 23 per cent.; while at Eschwege, 496 feet above the sea, it is only 12 per cent.; and at Brotterode, 1800 feet above the sea, it is 0.9 per cent.\*]

421. The second and third questions are partly answered by what I have now stated; for although a continued residence in these climates may not be injurious to many consumptive patients, yet it may give rise to diseases of a different nature, or may occasion complications of phthisis which otherwise might not have occurred; or it may prove too exhausting, or otherwise injurious to the patient: in many cases, if not in the majority, a change to a more temperate climate is therefore beneficial before the hot season commences; and if the change can be made to a climate both dry and temperate, it will generally prove of the greatest advantage. Patients who are subject to hæmoptysis, or other states of the more usual or the chronic forms of phthisis, will derive very great benefit from a voyage to Alexandria, and a journey thence to Cairo and Upper Egypt, and, having resided there or in Nubia some time, proceeding thence to Syria, they may return by Malaga, Granada, or other places in Andalusia, in April or May, to England; or, if it be preferred, a voyage may be made across the Atlantic early in September with great benefit; and having crossed the isthmus of Panama, the Pacific may be traversed; and having visited Lima, a residence in the mountains of Peru may be tried at the elevation and in the season found most beneficial for phthisical patients. After a satisfactory residence in this locality, the patient may return to Europe by the same route as that by which he went out, or by one more direct, taking care, however, to return to England about May or June.\* If this

\* There are many places in the south of Spain that may be chosen for winter residences by persons either threatened by or in the first stage of tubercular consumption, especially in Andalusia; and if the vicinity of Malaga, or of Granada, or of Seville be not selected, other places in the above extensive province may be tried. During the warmer months the more elevated situations on the southern side, or the southern ridges of the Sierra Morena, furnish many situations which cannot fail of possessing most of the advantages required by phthisical invalids.

Dr. MITCHELL (*Brit. and For. Medico-Chirurg. Rev.*, No. xxxiii., p. 226) states that "the climate of Algiers, during winter and spring, vies with that of Madeira, being as warm and steady in temperature, but drier and more bracing."

It has been a generally received opinion among medi-

plan be followed out for two, or three, or four seasons, at an early stage, with due precautions

and scientific men that very high elevations above the level of the sea are injurious to tubercular consumption, especially when it is either ushered in, or attended by, or even threatened with hæmoptysis. Dr. ARCHIBALD SMITH's very interesting account of the very remarkable benefit he saw, in numerous cases (see above, § 420), derived from residing at an elevation above the sea-level of 5000 to 10,000 feet, completely upsets this opinion. This very able and experienced physician has farther remarked upon this subject, in a communication he has kindly favoured me with since the earlier pages of this article were published; and he has stated, respecting a diminished or increased frequency of phthisis in the aborigines of a country by change to a colder or to a warmer climate, or to a higher or lower elevation, "that, as regards Lima and the coast of Peru generally, the change to the maritime climates of Chili and Ecuador—the first colder, the second warmer—has a decidedly bad effect on the Peruvian phthisical invalid; but the higher elevation on his own mountains of 5000 to 10,000 feet has a decidedly curative influence. In these regions the climate is moderately dry and temperate, favourable to exercise in the open air, and the patient is also removed from a luxurious and sensuous society, as well as from a warm, humid, and relaxing atmosphere. Very possibly the decided benefit received by the natives of Peru from the change from coast to mountain may not be equally shared in by strangers. I hope, however, that this may be a fair trial, and, as you recommend navigating by Panama to the Pacific, that you will find room to recommend, on fair trial, to Europeans, the migration to elevated spots on the Andes, from time immemorial known of paramount importance to the native races affected with pulmonary consumption." Dr. ARCHIBALD SMITH's very long and extensive experience of the diseases in this part of the New World renders his opinion of the greatest value on this subject. He farther remarks: "I observe at § 218 what you say with respect to the effect of migration on the Chinese; and I can say that, among the thousands of this race lately introduced into Lima, I never met with an instance of phthisis. It is likely, however, that this disease will show itself in their offspring born in Peru of Indian or dark women. When the Chinese crop their hair and take on the Peruvian dress, it is not easy to distinguish them from native Peruvian Indians." Is not this last remark in favour of the opinion that the Indian races are offshoots from the Mongolian, or Chinese?

Dr. RICHARDSON, in his account of his travels in Egypt and Nubia, published more than thirty years ago, has strongly recommended these countries, and especially the latter, as winter and spring residences for phthisical invalids. The more recent evidence of my eminent friend, the Rev. Dr. BARCLAY, fully confirms this recommendation. The very interesting account given by Dr. BARCLAY of the climate of *Middle and Upper Egypt, Malaga, &c.*, is so very important to our profession and to phthisical patients, coming as it does from one whose great talents and acquirements I have long known and admired, that I quote it at this place without abridgment, of which, indeed, it does not admit:

"The object of this communication is to draw attention to those characteristics of the Egyptian climate by which an opinion may be formed of its curative influence in cases for which a removal to a milder and warmer atmosphere is usually recommended. The result of my own observation and experience, during five months spent in that country, is a thorough conviction that there is no accessible part of the world so well adapted for the relief of most of that formidable class of diseases to which the respiratory organs are subject. In venturing to express this opinion, however, I am far from affirming that all Egypt, or any part of Egypt at all seasons, fulfils the conditions required in a climate suitable for such cases. On the contrary, it will be readily perceived that no part of the Delta is at any season adapted to patients who are subject to these affections, nor, it may be added, to those who are either dyspeptic or rheumatic; and from the beginning of May to the end of September the heat in every part of Egypt is too great for a European constitution weakened by disease. But in Middle and Upper Egypt, from the beginning of October to the end of April, the invalid may breathe, under a bright and cloudless sky, an atmosphere at once of a warm and equable temperature, of perfect purity, and free from all excess of humidity. The climate of other regions may be equally distinguished by one or more of these properties (though even that is doubtful), but assuredly there is no other habitable part of the globe in which they are all combined in so great perfection.

"The malady for which I sought relief in a southern

against injurious exposure, the disease will either be arrested for some years, or altogether over-

climate was chronic bronchitis in its most aggravated form. All the usual remedies, both external and internal, had been resorted to and steadily persevered in, under the ablest medical advice, but with little temporary and no permanent benefit. I had tried with the same unfavourable result those places on the south coast of England which are usually recommended to invalids. The symptoms obstinately resisted every medical measure. The chronic character of the disease was frequently exchanged for attacks of a sub-acute form. These always commenced with inflammation of the pharynx, creeping insidiously down the glottis and trachea to the bronchial tubes, which became gorged with mucus throughout their whole extent, and on every spot on which the stethoscope could be planted over the lungs the mucous rûle was to be heard. Dyspnoea, accompanied with loud wheezing, was at all times distressing; but its nocturnal exacerbations, which invariably occurred after a short sleep, like fits of spasmodic asthma, were often so fearfully violent as to threaten suffocation. The digestive organs were deranged, I had no appetite for food, my frame was emaciated, and my strength prostrated.

"I was so enfeebled as to be unable to encounter the voyage till the month of November, and thus I lost two months of the season suitable for the residence of an invalid in that country. Yet the benefit which, by the blessing of Providence, I reaped from that delicious climate was most signal, and far exceeded all that my most sanguine hopes had ventured to anticipate.

"On the passage outward I stopped five days at Malta, but found the heat so oppressive in the daytime, and the chills in the evening so severe, that I was glad to make my escape. The extreme humidity of the atmosphere in that island, notwithstanding its high temperature, must always render it, I apprehend, an unfit resort for a bronchitic patient; and the greatness of the diurnal range of the thermometer, at least in winter, makes it questionable how far it is an eligible residence for consumptive patients. It is believed that an inquiry into results will not tend to give a favourable idea of its sanative influence on that class of complaints. Of the climate of Alexandria also I have reason, as I shall show afterward, to speak unfavourably. In Cairo, however, a very different climate was found; and I had not been many days there when I began to experience its effects in allaying the irritability of the respiratory mucous membrane. The coldest season there is the latter part of December and the early part of January; and though the temperature even then is equal to that of our best summer weather, yet the evenings are somewhat chill. The following observations, made with the register thermometer and Dollond's hygrometer, show the temperature and the dryness of the atmosphere at Cairo during the coldest fortnight of the year:

Date.	Lowest temp. by night.	Highest temp. by day.	Diurnal range.	Degrees dry.	Degrees damp.	State of weather.
Dec. 25.	50	64	5	7	..	Bright sunshine.
" 26.	58	63	5	7	..	Do.
" 27.	58	62	4	5	..	Do.
" 28.	57	60	3	..	5	Rain and blowing.
" 29.	57	60	3	1	..	Showery.
" 30.	58	60	2	..	4	Wind and rain.
" 31.	59	64	5	5	..	Bright sunshine.
Jan. 1.	60	64	4	8	..	Do.
" 2.	57	62	5	4	..	Cloudy.
" 3.	58	63	5	0	0*	Do. and blowing.
" 4.	58	64	6	5	..	Bright sunshine.
" 5.	57	64	7	4	..	Cloudy.
" 6.	58	61	3	..	4	Drizzling.
" 7.	57	60	3	..	1	Cloudy and windy.

"From these observations it will appear that, warm and equable as the winter temperature is at Cairo, the weather at that season is not free from frequent and sudden changes. It is in Upper Egypt that the invalid must seek entire exemption from these, and there he will not be disappointed.

"While I was there my register was kept on the Nile, and consequently it shows a lower temperature, at least in the night time, than would be denoted at a little distance from the river, while the dryness indicated by the hygrometer in the latter case was many degrees greater than that registered on the river.

\* The zero of the hygrometer corresponds to summer drought in Britain.

come, in a great many cases—indeed in most, if it be not delayed to a too far advanced stage.

[The following table shows the mean temperature for each season, each month, and the whole

year, at St. Augustine, Fort Brooke (Florida), Nice, Rome, Naples, and Madeira, for the years 1825, 1828, 1830, rejecting decimals :

Place.	Lat.	Mean Ann'l Temp-erature.	Mean Temperature of the Seasons.				Mean Temperature for each Month.											
			Winter.	Spring.	Summer.	Autumn.	Jan.	Feb.	Mar.	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.
St. Augus- tine . . .	29 48	72.24	62.85	70.55	82.05	73.56	62.15	64.97	66.53	68.68	76.44	81.12	82.36	82.68	79.56	73.61	67.47	61.38
Ft. Brooke.	27 57	73.19	65.02	71.71	81.04	74.59	63.75	66.56	66.48	71.27	77.39	80.90	81.43	80.79	79.01	75.04	69.71	64.76
Nice . . . .	43 41	59.48	47.82	55.23	72.26	61.65	45.85	49.00	51.45	57.00	63.00	69.00	73.50	74.30	63.35	61.55	53.70	48.60
Rome . . . .	41 54	60.79	48.90	57.65	72.16	63.96	47.65	47.45	52.05	56.40	64.50	69.17	73.30	74.02	69.50	63.60	58.80	49.62
Naples . . .	40 50	61.40	48.50	58.50	70.83	64.50	46.50	48.50	52.00	57.00	66.50	71.00	75.00	76.50	72.50	65.00	54.50	50.50
Madeira . .	32 37	64.57	59.50	62.20	69.33	67.23	59.50	58.50	61.06	62.50	63.00	65.00	70.00	73.00	71.50	67.50	62.70	60.50

The above table shows very conclusively the superiority of the climate of Florida during the

winter and spring months to that of the most celebrated places of resort abroad.]

"The following table contains the result of the observations noted between Thebes and Asouan, the uppermost town in Egypt, and from these an idea may be formed of the winter climate in that region :

Date.	Lowest temp- by night.	Highest temp- by day.	Diurnal range.	Degrees dry.	State of weather.
Jan. 17.	64	70	6	7	Cloudless sky and bright sunshine every day; the firmament blazing with stars every night; no evening chills.
" 18.	63	68	5	7	
" 19.	66	70	4	5	
" 20.	64	60	5	12	
" 21.	61	71	7	7

" 23.	63	72	4	10	

"The benefit I derived from breathing the genial air of Thebeid was very decided. The periodical night attacks, though still occurring, were less violent and of shorter duration; my breathing was greatly relieved; and my strength was so far recruited that I was able, without fatigue, to make daily excursions, sometimes of many miles, to the monuments with which this part of the valley of the Nile is studded.

"At Thebes, which for several reasons should be made head-quarters in Upper Egypt, the day temperature, from the middle of January to the middle of February, ranges from 68° to 79°, and after the latter date the heat becomes rather too great to be borne with comfort. The invalid should then commence his downward voyage, and by the time he reaches the latitude of Cairo he will find the climate there nearly as delightful as that which he left at Thebes. My register during the first week of March at Cairo was as follows:

Date.	Lowest temp- by night.	Highest temp- by day.	Diurnal range.	Degrees dry.	Degrees damp.	State of weather.
Mar. 1.	66	72	6	9	..	Gentle breeze, sunny.
" 2.	67	74	5	4	..	Do. do. do.
" 3.	68	75	7	0	0	Fog.
" 4.	63	76	8	6	..	Calm and sunny.
" 5.	71	71	3	..	2	Haze.
" 6.	69	72	3	6	..	Cloudy and sunny.
" 7.	65	69	4	6	..	Drops of rain.

"In a city like Cairo, with a dense population of more than two hundred thousand people, and with narrow streets walled in by lofty houses, and constantly watered to lay the dust, the air can neither be so pure nor so dry as in the desert. Accordingly, the medical gentlemen of Cairo are in the habit of sending almost all their convalescent patients to reside for some time in the adjoining desert, to enjoy the benefit of its invigorating air. In it there is no water, either running or stagnant, to produce humidity by evaporation, nor is there any decaying matter, either vegetable or animal, to taint the air with noxious exhalations. It is in the desert, therefore, that the qualities of warmth, equability, dryness, and purity, which are characteristic of the Egyptian climate in general, are to be found in the most perfect union. The

soothing influence of the desert air on delicate organs of respiration, and its invigorating influence on a debilitated frame, can be appreciated by those only who, like myself, have experienced its marvelous effects. It is at once balmy and bracing; and the invalid, while breathing it, feels as if he were drinking in health at every pore. I quitted Cairo for the desert of Ghezeel on the 12th of March, and took up my abode in the neighbourhood of the Pyramids; and there a sudden change came over me, as if by magic. The second night I passed in the desert was marked by sound and uninterrupted sleep, and the absence of the periodical fit of dyspnoea, the first occasion on which I had enjoyed the one or had been exempted from the other for more than two years. My appetite soon became excessive; both the flesh and the strength I had lost during my illness were restored; every symptom of my complaint disappeared, and at the end of a month I returned to Cairo in perfect health. The following table contains the meteorological register kept by me while I lived in the desert:

Date.	Lowest temp- by night.	Highest temp- by day.	Diurnal range.	Degrees dry.	State of weather.
Mar. 13.	63	69	6	10	High wind.
" 14.	63	70	7	12	Bright sunshine.
" 15.	63	68	5	12	Do.

" 8.	65	71	6	10	Bright sunshine.

"The only other place in Egypt whose meteorology it seems necessary to notice is Alexandria. When it is borne in mind that this city is surrounded on three sides by the Mediterranean Sea, and that on the land side it is enveloped by the Lake Marcotis, a moist atmosphere may be expected, and accordingly the degree of humidity indicated in the following extract from my register is excessive. In this respect the state of the atmosphere in Alexandria, during the early part of May, will be found to contrast remarkably with that of Cairo and its vicinity during the latter part of April; while the greater equability of temperature in the former city, both from day to day and during the twenty-four hours, is no less observable:

422. THE DIET in phthisis has been already discussed in general terms, and chiefly with respect to my own experience (§ 299–301), but a few authorities and particulars may be farther adduced at this place.—*a*. HIPPOCRATES advised, for phthisis, *animal food* to be taken in small quantity, and often, when fever is absent; and the opinion has been followed by SALVADORI, MAY, RUSII, VOGEL, ROLLO, and KINGLAKE. Animal fats, marrow, and fat meats were recommended by LANGE and BERTIN. The circumstances in which these may be adopted have been stated above (§ 299–301).

[Many physicians of the present day make but little if any discrimination in prescribing the diet and regimen of phthisical patients. The directions are to eat beef-steak, mutton, fat ham, butter, cream, and drink porter, ale, brandy, using

all the exercise possible in the open air; forgetting that the diet of consumptives must, as in other diseases, be regulated by the stage of disease and the circumstances of each particular case; in the early stages enjoining usually a milder diet, especially in cases complicated, as it often is, with inflammation. If the patient is able to take active out-door exercise, the food may be of a more nourishing quality, and in larger quantity, than if confined to the house; but we have almost invariably found that if the patient was chiefly confined in-doors, a rich diet of animal food excited fever, and aggravated the cough and other symptoms. Carbonaceous matters, however, must be supplied in sufficient quantity to combine with the oxygen taken in, otherwise the waste and loss of weight will be rapid. Sir JAMES

"Now far Alexandria, during the months of March and April, may be a more suitable residence than Madeira or Italy for those whose complaints require a climate at once warm, equable, and moist, I leave it to gentlemen of the medical profession to judge; but I do think myself fully warranted to denounce it as a most unsuitable place for a bronchitic patient. During all the time I was there I felt as if inhaling steam; my breathing was excessively affected, and my whole system was languid and relaxed. These effects, however, by the time I had been twenty-four hours at sea, were completely dispelled, leaving no doubt whatever as to their cause.

"I may add that dyspepsia is very prevalent among the European residents in Alexandria; and I was informed that cases of pulmonary consumption, though not common, do occasionally occur among the natives of the whole northern sea-board of Egypt; but the inhabitants of Middle and Upper Egypt, as far as I could learn, are entirely exempted from that fatal disease. The prevailing maladies throughout all Egypt are dysentery and ophthalmia, both induced, it is believed, by exposure of the heated frame to currents of cold air.

"These observations on the subject of Egyptian climate would be very incomplete if I failed to notice its influence in arresting hæmoptysis. Several instances of its efficacy in that respect were mentioned to me, and one very decided case fell under my own observation. A. B., a middle-aged gentleman, of a clear and florid complexion, had been for years afflicted with this complaint to an alarming extent. He had spent a winter in Italy without experiencing the smallest mitigation of his ailment. He had next been sent to Madeira, and there the malady was very greatly aggravated. He was at Malta when I went to Egypt; but finding no relief there, he came to Cairo in the end of December, and took up his abode at the hotel at which I lodged. The effect of the change of climate was immediate. The spitting of blood ceased at once, nor did it ever recur during his stay at Cairo, which was prolonged till the end of April. He then went to the south of Spain, and remained there till the month of June, when he returned to England, apparently in perfect health, and fully resolved to spend the whole of the following winter in Egypt with the view of confirming his cure.

"The transition from the climate of Egypt to that of

Britain is too violent to be hazarded by one whose respiratory organs are in a delicate or dubious condition, especially as the season at which it is necessary to quit the one country is far from being genial in the other. I therefore stopped in Spain on my homeward passage, and spent the latter part of May and the greater part of June in that country and in Portugal. Having heard that the air of Malaga was remarkable for its mildness, I repaired thither, and was both delighted and surprised to find in Europe a climate scarcely inferior in any respect to that of the latitude of Cairo. The register I kept while there, and from which I subjoin an extract, shows a temperature which was probably only a few degrees lower than that of Cairo at the same date, while its equability was greater than I had noted any where except at Alexandria; and, what is still more remarkable, the dryness of its atmosphere exceeds that of Cairo, and contrasts surprisingly with the humidity with which the air of Alexandria is loaded.

"The atmospheric conditions indicated by the following table are doubtless to be referred, partly to the geological structure and the physical conformation of the country around Malaga, and partly to the latitude in which it is situated. I am persuaded that, in a therapeutic point of view, the climate in this part of Andalusia is deserving of more attention than it seems hitherto to have received. Those who take it for granted that the climate of Italy must be the mildest and warmest in Europe seem to forget that Malaga is 248 miles farther south than Naples, 318 miles farther south than Rome, and 518 miles farther south than Venice; and those who have not adverted to the fact will probably be surprised to find that it is 5 miles farther south than Algiers. Both Gibraltar and Cadiz are somewhat south of Malaga, but both have a great diurnal range of temperature, and are nearly equal to Alexandria in the humidity of their atmosphere, the one standing on an almost insulated rock in the Mediterranean Sea, and the other on a narrow spur of land projecting into the Atlantic Ocean.

"In the beginning of June I moved northward to Lisbon, but on its climate and that of delightful Cintra no information is needed. In the end of June, 1853, I returned to Scotland; and though I was threatened soon after I reached home with a recurrence of bronchitic symptoms, these now yielded readily to medical treatment. I am most thankful to be able to add that during the last twelvemonth I have enjoyed excellent health, nor have I been affected during that time by any of the changes of weather to which our variable climate is subject."—*The Climate of Egypt*, by the Rev. THOMAS BARCLAY, D.D. Svo. Edinburgh, 1854.

CLARK is of opinion that "the cases likely to be cured by the stimulating plan of treatment—by beef-steaks and porter—bear a very small proportion to those who are injured by it."—Art. "*Tubercular Phthisis*," *Cyclop. Pract. Med., Am. ed.*, p. 570. This statement will hardly hold good, perhaps, when applied to the disease among us, although we are satisfied that more discrimination should be used in regard to the diet prescribed, and that injury is often done from neglect of due caution on this subject.]

b. *A fish diet* is often of service, especially in the more chronic and hæmorrhagic states, or when the biliary organs are congested; but on all occasions the white kinds of fish should be selected, and always be boiled. Oysters were praised by TULPIUS and SIMS, but they ought to be taken immediately upon being opened, and a small number only at one time.

c. *Vegetable food* has been advised by many writers in preference to any other, while as many recommend a due proportion of animal and vegetable diet. Of the more unusual articles, at least in this climate, new figs, dates, the nuts yielding the palm oil, olives, &c., are the most likely to be of service. Grapes, both recent and dried, were praised by RIVIERIUS; pickled red-cabbage by LANGE; and cucumbers, with vinegar and sugar, by SCHMALZ, FRIZE, QUARIN, MARX; but these last should be thus dressed without having had their outer rinds removed. Of oranges, lemons, limes, &c., the utility is manifest.

423. *d. Milk* has always received great commendation in phthisis, but writers have differed respecting that which is most beneficial. Thus ZACUTUS LUSITANUS and BLEGNY prefer human milk; ARETEUS, BURSERIUS, and STOLL, asses' milk; DIEMERBROECK and VELSCHIUS, goats' milk; SCHENCK, either asses' or goats' milk; HIPPOCRATES, either mares' or asses' milk; and HEISTER, the whey of cows' milk. STOLL considered that asses' and human milk should be diluted, and that they are injurious in the inflammatory complications and in the last stage of the malady. Whatever may be the diet and regimen adopted, milk of various kinds, in suitable forms and states of dilution, constitutes an important part of the treatment of phthisis.

424. *e. The beverages* allowed the patient should depend on the form and stage of phthisis. In an early stage whey is one of the best that can be taken. At a far-advanced stage, or if diarrhœa be present, it is apt to run off by the bowels. Fermented whey, or serum of milk, or the whey of butter-milk, or recent butter-milk, may be given according to circumstances. In northern or Scandinavian countries, and also among the Tartars, the fermented serum of milk is very commonly employed, and it has been recommended by SIEVERS and others. Spruce-beer is one of the best beverages that can be used; weak tar-water is also sometimes beneficial. Seltzer-water, with milk, and lime-water or Carara-water, with milk, when the bowels are much relaxed, are also of service.

425. *f. In recommendation of exercise* in the open day, according to the strength and state of the patient, it is unnecessary to add any thing to what has already been stated. Of all kinds of exercise, walking and horse-exercise are the best. Although the latter was considered of little use by QUARIN, yet by SYDENHAM, HALLER, MARX, DARWIN, and others mentioned in the historical

sketch (§ 214, *et seq.*), it was strongly recommended. STOLL advised it in the non-inflammatory states, and when the abdominal viscera were torpid or congested. In the inflammatory complications, active exercise, either on horseback or otherwise, can rarely be taken.

426. In concluding the above imperfect view of the treatment of phthisis, it will be manifest that no one plan of cure, class of medicines, kind of diet, or regimen—no single method, whether medicinal or regimenal, or both, is appropriate to all cases, or even to the great majority of cases, of phthisis. The rational physician, after having endeavoured to ascertain the existing morbid conditions, will merely select and combine, from the stores above indicated, such means as he believes to be most energetic in arresting, counteracting, or removing these conditions, as far as circumstances may warrant the attempt or may promise success.

(See also *Bibliog. and Refer.* to art. on SCROFULA AND TUBERCLES.)
- [AM. BIBLIOG. AND REFER.—*Samuel G. Morton*, Illustrations of Pulm. Consumption, its Anatomical Characters, Causes, Symptoms, and Treatment, to which are added some Remarks on the Climate of the United States, the West Indies, &c., with 13 col'd plates, Svo. Philad., 1837 (one of the best works on this subject).—*Benjamin Rush*, Medical Inquiries and Observations, 4 vols. in 2, 5th ed. Phil., 1819. Dr. Rush recommends particularly long journeys on horseback for the cure of this disease; also, in particular cases, stimulants and tonics, as *copaiba, bals. Peru, oil amber, turpentine, tar, garlic, eliz. vitriol, dandelion, houndswort, wild cherry bark, cinchona bark, cold bath*, &c.; also a cordial and stimulating diet, dry air in elevated situations, *remote from the sea in all cases*; appropriate clothing, blisters, and issues in the inflammatory stage, moderate use of the lungs, salivation, and in some cases bleeding. For cough, *demulcent teas, strips and lozenges, opiates, tar vapour*, &c.; for night sweats, *eliz. vit. and lime-water*; for diarrhœa, *chalk julap*, with *tinct. opii* and *tinct. cinnamon*, and astringent injections. The above are called palliatives. The radical remedy is long-continued horseback exercise.—*Wm. Sweetser*, a Treatise on Consumption, embracing an Inquiry into the Influence exerted upon it by Journeys, Voyages, and Change of Climate, with Directions for the Consumptive visiting the South of Europe, and Remarks upon its Climate, Svo. Bost., 1836, p. 24. This work, adapted for general reading, is written in a pure classical style, and is one of the most instructive on this subject in our language. The remarks on the best modes of prevention and the climate of different places in Southern Europe, the result of the author's personal observations, are worthy of the particular attention of the American reader.—*John Bell* and *W. Stokes*, Lectures on the Theory and Practice of Physic, 2 vols., Svo. Phil., 1848, 4th edition. Dr. Bell has embodied a vast amount of facts and personal observations in regard to this disease in seven lectures devoted to it, which may be found in the 2d vol. The treatment recommended is judicious, and in accordance with the present prevailing doctrines on this subject.—*Parish*, North Am. Med. and Surg. Journ., vol. viii. Dr. P., following in the footsteps of Dr. Rush, recommends the tubercular invalid "to rough it" on horseback, on long journeys and in all kinds of weather, as the principal mode of cure.—*Samuel Forry*, The Climate of the United States and its Endemic Influences, Svo. New York, 1842.—*Horace Green*, a Treat. on Diseases of the Air Passages, Svo. N. Y., 1846; also Report on the Use and Effect of Applications of Nitrate of Silver to the Throat, either in local or general disease, Trans. of Am. Med. Assoc., 1856; also Am. Med. Month. for Jan., 1855, and March, 1856, and Trans. of N. Y. State Med. Soc., 1855, &c.—*Lenuel Shattuck*, Report of the Sanitary Commission of Massachusetts, 1850, Svo. Mr. S. has embodied in his report some very interesting facts in regard to the prevalence of consumption in Massachusetts. He shows from the statistical reports that the seasons do not exert much influence upon the disease, especially its terminating period. In four years, from 1845-8, there were 3443 males and 5384 females died of this disease in Massachusetts, of whom 533 females were under 15, and 464 males; over 60,916 females, 753 males; from 20 to 30 the number of females who perish from it is nearly double that of the males. In the country towns the proportion of the sexes is as 39.01 males to 60.99 females; in New York city, as 42.08 to 57.92. What are the peculiar causes affecting females in the country predisposing them to the disease? The proportion of deaths from phthisis in the western counties does not vary much from that on the sea-coast, being 1 in 3.92 in Barnstable county, to 1 in 5.43 in Berkshire. As 5.935, one tenth of the whole, are returned without a specified cause, the proportion of deaths from consumption in Massachusetts must be somewhat greater than the above (*loc. cit.*).—*H. Hunt*,

Observ. on a Change of Climate in Pulm. Consumption, North American Med. and Surg. Journ., vol. i., p. 282.—*Thomas Henderson*, Cases of Pulm. Consumption, Am. Journ. of Med. Science, vol. viii.—*N. S. Davis*, in Trans. of Illinois Med. Soc., 1856, on Alcoholic Liquors in Tub. Consumption.—*Wm. M. Fahnstock*, in Am. Journ. of Med. Sci., vol. v., p. 366.—*John Spence*, Case of Pulm. Consumption, showing the Influence of a Sea Voyage on that Disease, in *Ibid.*, vol. ii.—*G. W. Steadman*, Case of Tub. Consumption, in which milky urine was voided, in *Ibid.*, vol. ii., p. 295.—*James Stewart*, on the Lungs and their Diseases. New York, 1849. In this small work Dr. Stewart shows that in all classes of animals there is found a certain relation between the composition of the body and the development of the apparatus of respiration, which explains very clearly the production of scrofula and tubercle by breathing too little or too foul air. He shows that in the lowest form of organization albumen predominates greatly over all other animalized substances, the proportion being diminished as animals rise in the scale of being. In those of the lowest organization respiration is least active, and as they rise in the scale respiration becomes more and more elaborate; so that the greater the proportion of albumen in the animal, the less important is the function of respiration, and the less the proportion, the more complicated, more developed, and more important is this function. Now, as tubercle and scrofula consist almost wholly of albumen, Dr. S. supposes that from a want of sufficient oxygen, where too little air is respired, or from inhaling an impure air, the albumen is not converted into healthy animal tissue, but deposited in the lungs, glands, &c., in its nearly pure form, constituting tubercular or scrofulous disease. Hence the deleterious influence of certain occupations which restrict the movements of the chest, as tailoring, engraving, shoemaking, &c., as well as tight lacing.—*John H. Griscom*, The Use and Abuses of Air, 12mo. N. Y., 1850, p. 249. In this work Dr. G. has most ably pointed out the influence of air in sustaining life and producing disease, with remarks on the ventilation of houses, and the best methods of securing a pure and wholesome atmosphere inside of dwellings, churches, court-rooms, workshops, and buildings of all kinds.—*Samuel Henry Dickson*, Essays on Pathology and Therapeutics, 2 vols. Svo. Charleston, 1845.—*Austin Flint*, Physical Exploration and Diagnosis of Diseases affecting the Respiratory Organs, Svo., p. 636. Philad., 1855. The ablest work on the subject yet published; also Prize Essay "on Variations of Pitch," Trans. Am. Med. Asso., 1854.—*George B. Wood*, a Treatise on the Practice of Medicine, 2 vols., Svo. Phil., 1847.—*Meredith Clymer*, Notes and Additions to "A Practical Treatise on the Diseases of the Respiratory Organs," &c., by C. J. B. Williams, Svo. Phil., 1845.—*Henry J. Bourditch*, "Revisions and Alterations" of Pathological Researches on Phthisis, by P. Ch. A. Louis, Svo. Bost., 1836; and the Young Stethoscopist, Cases of Anomalous Development of Tubercles, &c., Am. Med. Monthly, N. Y., 1855 (1 to 150 at base of lung).—*Robley Dunglison*, The Pract. of Med., &c., 2 vols., Svo. Phil., 1848.—Notes to Am. edition of Cyclopaedia of Practical Medicine. Phila., 4 vols., Svo; and "Human Health," &c., &c.—*D. F. Condie*, Notes to Watson's Practice of Physic, octavo. Phil., 1844.—*O. W. Holmes*, Notes to Am. ed. of Marshall Hall's Pract. of Medicine, Svo. Bost., 1845.—*N. Chapman*, Lectures on the more important Diseases of the Abdom. Viscera, Svo. Phil., 1845.—*John A. Swett*, on Dis. of the Chest, Svo. N. Y., 1850. Cases of Thoracic Disease in which the diagnosis was attended with unusual difficulties, in New York Journal of Med., July, 1845.—*David Hosack*, Lectures on the Practice of Medicine, Svo. New York; and in Am. Med. and Phil. Register, 4 vols. New York, 1813, '14, '15, '16. Dr. Hosack was a strong advocate for bleeding, blistering, and emetics, "in the first or inflammatory stage," as he considered it, followed by mercurial salivation, and tonics in the suppurative stage, in this respect following Dr. Rush.—*George P. Cammann* and A. Clark, a New Mode of ascertaining the Dimensions, Form, and Condition of Internal Organs by Percussion, in New York Journ. of Med., vol. iii., p. 62, 1840.—*R. L. Allen*, a Historical, Critical, and Ther. Analysis of the principal Mineral Fountains at Saratoga Springs, together with General Directions for their Use, 18mo., p. 271. Saratoga, 1844. Dr. A., though a resident at the Springs, remarks as follows: "I have never seen a case where I thought there was even a degree of palliation produced by a use of the water in pulmonary phthisis; but, on the contrary, always injurious, increasing all the alarming symptoms of this most formidable disease." Again: "My advice to all who are labouring under the corroding influence of this disease is, not to drink of any one of our mineral fountains, recently or remotely discovered and brought into notice."—*William A. McDowell*, Some Physiological Evidences of the Curability of Tubercular Consumption, in New York Journ. of Med., vol. x., p. 32. Under the head of "Therapeutical Resources for Promot-

ing the Removal of Tubercles," Dr. McD. states that "they must consist mainly of such articles as best promote the transformation of albumen of the blood into red globules; and of these the most important are iron, alcohol, naphtha, iodine, animal food, and common salt."—*W. H. Hyford*, on the Physiology of Exercise, Am. Journ. of Med. Science, vol. lix., 1855, p. 32.—*J. P. Hall*, Pulm. Lesion treated as an event arising in the Progress of Constitutional Decline under the Tubercular Diathesis, in *Ibid.*, July, 1855, p. 50.—*C. G. Conneys*, on the Etiology and Curability of Phthisis Pulm., in Transact. Ohio State Med. Soc., 1855.—*L. M. Lawson*, Pract. Observat. on the Diagnosis of Phthisis Pulmonalis, in *Ibid.*, 1855. Dr. L. doubts the existence of the supposed antagonism between a miasmatic influence and the production of tubercular diseases, and states that such diseases are not infrequent in miasmatic districts.—*G. R. Grant*, Report to Am. Med. Asso. (in Trans. of *Ibid.*, 1858) on Epidemics of Tennessee and Kentucky. Dr. G. states that phthisis pulmonalis is as common in malarial as in non-malarial regions, and that the disease is very common and fatal in Memphis, Tenn., the place of his residence, "where malaria is almost as common as in the Pontine Marshes." "One half of the 54 cases reported to have died of it occurred from July to October, the season when malaria is most prevalent." He also remarks, that as far south as 35th degree of latitude, in a region notoriously subject to malarial diseases, pneumonia and consumption occasion 25 per cent. of the mortality.—*D. Drake*, The Diseases of the Interior Valley of North Amer., 2 vols., Svo. Cin., 1850. (Dr. D. also states that "in those regions where periodical fevers prevail, consumption is also a prevalent disease")—one of the most elaborate and able works on medicine ever published in our country.—*W. A. Hammond*, U. S. A., The Physiological Effects of Alcohol, &c. (As connected with the question of the use of alcohol in tubercular diseases, the results of experiments on the healthy body are worthy of record in this connexion. The chief conclusions arrived at are, that alcohol increases the weight of the body by retarding the metamorphosis of the old tissues, promoting the formation of new, and limiting the consumption of fat. Under the use of alcohol, the carbonic acid and aqueous vapour given off in respiration were lessened in quantity, the amount of feces diminished, the quantity of urine reduced, and the urea, chlorine, and phos. and sulph. acids diminished in amount.)—*D. D. Saunders* and *John C. Draper*, on the Value of the Red Line of the Gum in the Diagnosis of Consumption, New York Journ. Med., Jan., 1857. (The conclusions from an examination of several hundred cases of phthisis are: 1st, that the red line, though it occurs frequently in phthisis and chronic blood diseases, is by no means characteristic of them; 2d, that in pregnant and recently delivered women the line occurs more frequently and better marked than in any other cases; 3d, that age or sex exercises no influence on the existence of the line.)—*S. B. Hunt*, Editorial in Buffalo Med. Jour., Nov., 1856, on the Use of Alcohol in Phthisis. (Dr. H. advocates its use on the grounds that it is a carbonaceous food, that it stimulates the pancreatic secretion, that it acts as a substitute for pancreatic juice, emulsifying the fat in the stomach, and, lastly, that it improves the whole digestive function by its influence over the stomach, &c., through the coeliac plexus).—*George Bartlett*, Topical Treatment of the Respiratory Passages, Boston Medical and Surg. Journal, 1850.—*Jules Richard*, on the Influence of Sea Life and Warm Countries on the Progress of Pulmonary Phthisis, Am. Med. Monthly. N. Y., 1856. Dr. R., from much experience in the French Navy in various parts of the world, concludes that sea voyages accelerate the progress of pulmonary tubercularization much more frequently than they retard it; that it is a very common disease among sailors, much more so, indeed, than in the army; that phthisis progresses aboard ship much more rapidly than on land. He advises that young men threatened with phthisis should be interdicted the naval profession, and expresses the opinion that warm countries, especially within the tropics, are very prejudicial to consumptives, though there may be a few places on the confines of that region, and concentrated in a narrow space, which may be exceptions; and that if change of climate ever does good in phthisis, it is in the first stage.—*W. W. Gerhard*, Remarks on Tubercular Affections, &c., Am. Journ. Med. Sci., N. S., vol. xxi., p. 368.—*A. Stille*, Review of Fourcault on "Chronic Diseases," in Am. Journ. Med. Science, vol. x., N. S., p. 359.—*Charles Hildreth*, on Cinchona and Iodine in Phthisis Pulmonalis, in *Ibid.*, vol. iv., N. S., p. 251.—*J. B. S. Jackson*, in New England Quart. Journ. of Med. and Surg., 1842. Dissections of 604 cases of persons dying of all diseases in 10 years in Boston. Dr. J. states that intemperance does not appear to develop phthisis, and that of 35 drunkards 26 presented no signs of tubercle.—*Andrew Hamnerley*, Prize Essay on the Remote and Exciting Causes of Phthisis Pulmonalis, American Medical

1. CLASSIF.—4th Class, 6th Order (Cullen). 6th Class, 2d Order (Good). I. CLASS, I. ORDER (Author in Preface).

2. DEFINIT.—An inordinate generation and accumulation of a gaseous fluid within the digestive canal, generally with retention of it, occurring chiefly symptomatically, either terminating acute disease, or complicating chronic affections, and occasioning great abdominal distention, and a drum-like sound on percussion.

3. I. PATHOLOGY.—*Tympany* is generally the result of greatly impaired vital power, as manifested chiefly through the organic or ganglionic nervous system upon the digestive canal, whereby not only is the tonicity of the coats of the canal remarkably impaired, but also gaseous fluids are exhaled from the digestive mucous surface. That the air is generally contained in the canal, where it is retained either by spasm in parts of the canal near to its outlets, or by the inability of the muscular structure of the canal to expel it, cannot be doubted. It has been supposed by some writers that the air may be on some occasions exhaled into the peritoneal cavity. If this occurrence take place at all, it must result from the decomposition of matters effused into the cavity, as in cases of chronic peritonitis, or of puerperal peritonitis, or of perforation of the intestines, when some of the intestinal contents have passed into this cavity. The occurrence of tym-

pny from these changes is however, rare, but less rare when the intestines are perforated by any of the causes of this lesion of the intestines. (See art. *INTESTINES*, § 29.)

4. Several varieties of tympany have been enumerated by writers of the seventeenth and eighteenth centuries, according as the gaseous accumulation has occurred in the advanced course of acute maladies, or has complicated chronic diseases, the primary affections, with which tympany is associated, furnishing the basis of arrangement. Of these it is quite unnecessary to take any notice, as such occurrences of tympany are merely contingencies of advanced and dangerous diseases, and are merely symptoms of these or of hysterical or uterine disorders; often, however, assuming very prominent and distressing characters, especially in the last stages of peritonitis, of puerperal and malignant fevers, &c.. That the air which accumulates in the digestive tube in these and various other circumstances of disease cannot arise, to any great amount, from the decomposition or retention of alimentary materials, or of morbid secretions accumulated or retained in the canal, is demonstrated by the absence of these sources of the gaseous collection in the more extreme cases. We are compelled, therefore, to view the accumulation of air as the result of a morbidly increased exhalation of it from the digestive mucous surface, resulting from depressed vital or organic nervous power, in connexion with lost or impaired tone of the muscular coats of the canal; this last condition, equally with the augmented exhalation, proceeding from the loss of vital power. According to this view *tympany* is merely an extreme state of *flatulence* (see that article), the gaseous exhalation having accumulated in the former, so as to produce extreme distention, but being discharged in the latter at intervals or absorbed.

5. That this exhalation must necessarily proceed from the blood, in great measure, or, in as far as it does not arise from the decomposition of alimentary matters, or of the secretions, must necessarily be inferred, particularly in the more extreme and sudden accumulation of the gaseous fluid. JOHN HUNTER and CULLEN believed that the fluid was thus generated, and MAGENDIE and GERARDIN endeavoured to prove the occurrence by experiment. They included a portion of intestine between ligatures, returned it into the abdomen, yet air, nevertheless, was found in it, although it contained no materials for the generation of air. That the air was exhaled from the digestive mucous surface had long been believed in, and supported by observation and analogy. FABRICIUS HILDANUS, HOFFMANN, PORTAL, VIDAL, GASPARD, NYSTEN, MERAT, and many others, have contended for this doctrine, and have adduced facts in support of it. BICHAT has shown that friction with sulphur communicates the odour of sulphureted hydrogen to the gas which collects in the bowels. The swimming-bladders of fishes are known to be supplied with air from the blood only; and BLAINVILLE, DUMAS, MAGENDIE, and others, have shown that a division of the pneumo-gastric nerves is followed by gaseous distention of the stomach.

6. Tympanitic distention of the abdomen may therefore be referred, firstly and chiefly, to the extrication of air from the digestive mucous surface, owing to the states of organic nervous en-

downment, or to the irritation or morbid action of matters received into the alimentary canal, as in various kinds of poisoning, or to changes in the blood itself; secondly, in a small degree, from the deglutition of air with the food or with the saliva; and thirdly, and in a very variable degree, from the decomposition or fermentation of alimentary matters, or of secretions and excretions. In cases of weak digestion, or when the organic nervous influence is much depressed, the quantity of air which may be formed, as shown by Dr. HALES, from the fermentation of fruit or raw vegetables in the stomach is often very great.

7. According as either of these sources of gaseous collections in the digestive canal predominates or is increased, so may the nature of the gaseous fluid be supposed to vary. The states of the blood, the nature of the ingesta, whether alimentary, medicinal, or poisonous, the seat of the collection, will severally modify the composition of the gaseous fluid. MM. JURINE and CHEVREUL have shown that generally the proportions of oxygen and carbonic acid decrease, while that of nitrogen increases, in descending from the stomach to the rectum.\* Although there does not appear to have been any analysis of the air collected in tympany, yet there is every reason to infer that it does not materially differ from that usually formed in the digestive canal, unless under the influence of acute or malignant diseases, when, with an admixture of carbonic and nitrogenous gases, and a little hydrogen, sulphureted, carbureted, and even phosphoreted hydrogen, may severally exist in varying proportions.

8. II. THE CAUSES OF TYMPANY—*whether predisposing, exciting, concurring or determining*—are in some respects the same as those which are noticed under the head FLATULENCY; but they exist in the former, or are rather associated, with one or more of the following pathological states: 1st, with mechanical or other obstruction to the discharge of the gaseous exhalation from the alimentary canal; 2d, with impaired or lost contractile power of the muscular coats of the canal; 3d, with alterations of the blood from absorbed matters or from vital changes, affecting the absorption of gases from the air, or the generation or extrication of them from the blood; 4th, with changes in the circulation in the lungs, and in the respiratory functions. Where one or more of these conditions are present, and in proportion

as they are increased by depression or exhaustion of the vital manifestations or endowments of the digestive canal, in so far will the tympany become remarkable or extreme, and the possibility of its removal be diminished.

[There are two principal sources of flatulence; the first, chemical changes in the ingesta; second, secretion, or exhalation from the mucous membrane of the gastro-intestinal surface. There is also a third cause, not usually recognised, but of the reality of which we are fully satisfied from careful observation, and that is inefficient action of the liver, and a want of bile in the intestines. In a considerable proportion of the cases of flatulence which have come under our notice, we have found it relieved by medicines which promoted the hepatic secretion, as small doses of blue-pill or calomel. These cases are often associated with constipation, a furred tongue, foul breath, &c., all pointing to hepatic torpor, and the flatulence as well as the other symptoms are very certainly relieved by mercurials. In retrocedent gout, where the disease is transferred to the stomach and intestinal canal, attended, as it usually is, with very painful cramp of the stomach, colicky pains, constipation, and great flatulence, we have found large doses of calomel very successful in affording relief. In a case of this kind which recently came under our care, where the disease suddenly left the extremities and fastened on the digestive organs, and where the pain, flatulence, gastric sensibility, and cramp were so severe as to threaten the life of the patient, perfect and permanent relief was afforded by the administration of calomel, at first in large, and afterward alterative doses, which resulted in bringing away large quantities of thick, black bile. It is very probable there may be here, as in gastro duodenitis, a complete temporary occlusion of the mouth of the ductus communis choledochus, from vascular congestion of the duodenal mucous membrane, thus causing an obstruction to the flow of bile, and leading to flatulence, flatulent eructations, &c. In the flatulence accompanying ordinary dyspepsia, an alterative pill of blue mass, aloes, rhubarb, and gentian, will generally afford relief. The flatulence of low fevers may be due to exhalation, or to the play of the ordinary chemical affinities in the aliment or excretions in the stomach or intestines, from the low condition or suspension of organic nervous power. On the same principle we may perhaps account for the eructation of air in gastritis, hepatitis, &c., although it is more probable that in such cases it is the result of exhalation or secretion.]

9. The causes of tympanites, or rather the circumstances in which flatulent distention of the abdomen chiefly occur, are pathological, or consist of antecedent disorders or most dangerous organic changes. While such disorders are productive of the less severe and dangerous states, or those which more nearly approach the conditions described under the head Flatulence, the most dangerous organic changes and malignant maladies give rise to the extreme instances of meteorismus or tympany. The *slighter* cases of flatulent distention are produced by the nature of the food, especially by saccharine and acescent matters and vegetables, by indigestible and otherwise injurious articles of food, by constipation or the retention, by mechanical or vital obstruction, of the intestinal excretions, as in cases of

colic and ileus, and by hysteria or uterine and spinal irritation.

10. The *extreme* instances of tympany occur chiefly after poisonous ingesta, more particularly after poisonous meats, poisonous fish and shell-fish, and indeed during the last and most dangerous stage of poisoning by other deleterious agents (see *art.* Poisons generally, and especially § 427-528); in the advanced stages of puerperal fevers and puerperal peritonitis; in gastritis and interitis, particularly when perforation of the intestinal canal has taken place, and then air may escape into, or be developed in, the peritoneal cavity; in misplaced gout of the stomach or bowels; and in the last stage of adynamic and typhoid fevers, and of malignant continued and eruptive fevers. They also occur as terminations of fatal ileus, of hernia, of intersusceptions and strictures of the bowels, of lead colic, &c. Even a moderate degree of tympanitis in adynamic or typhoid fevers should be viewed with alarm, inasmuch as it is an indication of ulceration of PEYER'S glands.\*

11 III. The signs and symptoms of gaseous distention of the abdomen are very manifest, and even the seat of distention may be correctly inferred, especially when it is not extreme.—A. Palpation and percussion, in some cases even simple inspection, of the abdomen, are sufficient to show the seat and nature of the morbid condition. When the distention is chiefly of the stomach, the region of this organ is elevated above the margin of the false ribs, and the ensiform cartilage is protruded, the lower abdominal regions being less prominent. A similar elevation of the upper regions of the abdomen exists when the colon is the chief seat of distention, but the course of the colon, from the distended cæcum to the termination of the bowel, may be observed on inspection; and it is farther evinced by the hollow sound on percussion, especially when the cause of obstruction to the escape of flatus exists in or near to the sigmoid flexure or rectum. In the extreme instances of tympany, arising from any of the causes stated above (§ 8-10), the inflation is generally greatest in the small intestines, although it may be more or less in other portions of the digestive tube. In cases of hysteria, the distention is more limited, varies in its seat, and in the sympathetic sensations and pain it occasions; and owing to the spasm and contractions, successively affecting different portions of the tube, occasions borborygmi, and the propulsion of flatus into the stomach and œsophagus. The

mechanical effects of abdominal inflation are chiefly the pressure of the diaphragm on the heart, lungs, and large veins, and the arrest of the peristaltic motions of the intestine and of the propulsive efforts by which the intestinal contents are excreted. To these various subordinate effects others may be added, consisting of disturbance and arrest of the several secreting and excreting functions, of congestion of the lungs and large vessels, and of imperfect oxygenation of the blood, &c.

12. B. The *source and nature* of the abdominal inflation are to be inferred chiefly from the history of the case; from the antecedent disorder; from the seat, nature, and duration of pain; from the indications furnished by percussion of the several abdominal regions, and from the states of the excretions and of the pulse and tongue, with the various constitutional symptoms.

13. The flatulent distention is generally that of the intestinal canal, and not of the peritoneal cavity, although I would not say that this latter may not in rare cases be its seat, especially if the fluids effused into this cavity undergo more or less of decomposition previously to dissolution; but it is not improbable that the instances of gas thus evolved in this cavity, as observed by HEISTER, DUSSEAU, LIEUTAND, MORGAGNI, PORTAL, and others, are merely those in which the gas had escaped into the cavity owing to a perforation of the digestive canal. Tympanites has been occasionally observed in most of the organic lesions affecting the biliary organs, the digestive tube, and the abdominal and pelvic viscera. It is often an attendant on gout of the stomach or intestines.

14. C. The *appearances* observed in fatal cases are a very large proportion of those lesions which have been very fully described under the heads DIGESTIVE CANAL AND INTESTINES. In some cases the distention of the tube has been remarkably great throughout the greater part; and in others it has been more limited; as to the CÆCUM and COLON (see *those articles*). It has rarely been such as to rupture the bowel, sphacelation of the more distended portions being more common. The small intestines, especially the ileum, are always remarkably distended by flatus, and the glands, more particularly PEYER'S, are often more or less ulcerated, &c.

15. IV. THE TREATMENT of *tympany* is generally difficult, often hopeless, and always dependent upon the pathological conditions of which it is merely a symptom or contingent effect. In many cases it is productive of so much and so urgent distress that it becomes requisite to attempt the removal, or the amelioration of it, before the morbid states, from which it results, should occupy our attention with the view of directing the means of cure to them more especially. The *indications* are, therefore, 1st, to remove the tympanitic distention by such means as we possess, when it is distressing and most urgent; and, 2d, to subdue the pathological states upon which the distention depends, by appropriate treatment, either when this urgency is removed or does not yet exist.

16. i. The *removal of the flatulent distention* of the intestines by mechanical means was first recommended by Dr. DARWIN to be attempted by the introduction of an enema-pipe into the rectum, in order to remove the resistance of the sphincter ani to the passage of flatus. TRNKKA

\*AUSTIN FLINT, in an analysis of 56 cases of continued fever, reports tympanites present in 16 out of 23 hospital cases of *typhoid*, and in 8 out of 13 cases of *typhus* fever (*Clin. Rep. on Contin. Fever*, p. 84), being about an equal ratio in both, or as 4 to 6. In private practice it was less frequently observed. In *typhoid* fever it was accompanied in a majority of cases with diarrhoea; in *typhus* the diarrhoea was uniformly absent. In no case was this symptom considered to be present, except where there was obvious distention of the abdomen, as well as resonance on percussion.

In a second analysis of cases of continued fever, Dr. F. found tympanitis present in 22 out of 39 cases of *typhoid* fever, or in both collections 34 in 47 cases. In 5 cases the tympanitic distention was slight or moderate in 13, and considerable in 4. Of 10 cases of *typhus*, tympanitis was present in 8, being slight in every case but one. It was less marked in *typhus* than *typhoid*. Of 7 fatal cases of *typhoid*, it was present in 6; in one fatal case it was slight, in 3 moderate, in 2 considerable. Of 4 fatal cases of *typhus*, it was present in 3, but slight in each. The results show that this symptom occurs in a much larger proportion of cases ending fatally than of those in which recovery takes place.]

proposed that the gas should be removed by the air-pump; and Dr. OSBORNE, of Dublin, adopted this means, in the mode most likely to render the recommendation successful. After other means had failed, he introduced a gum-elastic tube of nearly three feet in length, with a button and hole at its extremity, and, having applied to it a stomach-pump, he proceeded to withdraw the gas, and "was enabled to do so with few interruptions, which were speedily overcome either by shifting the place of the tube in the intestine, or by injecting warm water to clear the holes by accidental stoppage. In about an hour the abdomen was reduced to nearly the natural size."—(*Lond. Med. Gaz.*, vol. vii., p. 825.) Dr. GRAVES employed similar means with success in two cases.—(*Lond. Med. and Surg. Journ.*, vol. ii., p. 781.) I had recourse to it in one case with temporary benefit, and have advised it in consultation in two or three instances, but in neither with permanent advantage. It should not, however, be neglected, as more or less relief is produced by it. In many of the more severe cases I have prescribed enemata containing the extract or confection of *rue*, or *asafetida*, or both *rue* and *asafetida*, and enemata with *oleum olivæ* and *oleum terbinthinae*, or the other carminative injections recommended for the removal of obstinate CONSTIPATION.

17. While the operation of these and similar means is expected, *frictions* over the abdomen with either of the *liniments* referred to in the APPENDIX (F. 311) may be resorted to, and medicines may be exhibited by the month. When the tympany is not attended or caused by mechanical obstruction, and is to be imputed rather to a paralyzed state of the muscular coats of the canal than to either constriction or strangulation, then the extract of *nux vomica* in small doses, or the usual carminatives, especially *rue*, *asafetida*, capsicum, turpentine, &c., are often of service. Turpentine, either as a confection or as a draught, with the *oleum olivæ*, or *ol. ricini*, on the surface of an aromatic water, or of common gin, in cases of hysterical tympany, or of spirit-drinkers, if prescribed with discrimination, is the most efficacious, especially if enemata or liniments with this substance be employed also.

18. When the tympanitic distention has arisen from obstruction in the vicinity of the cæcum or in the large bowels, then the injections into the latter should consist chiefly of warm, oleaginous, and saponaceous substances. Olive oil in large quantity may be thus employed, and this oil may be taken in small and frequent doses, oleaginous frictions being also resorted to. In several instances where tympany was caused by the obstruction arising from hysterical pica—by chewing paper in two cases, by sealing-wax in one case, and by bleached wax and spermaceti in another, the obstruction was removed, in all, by these means, the causes of the disorder having been made apparent, by the numerous balls of these substances, agglutinated by the mucus of the bowels, and moulded in the cells of the colon, which were voided.

19. ii. Having removed the more urgent symptoms, the *Pathological conditions* producing the tympany requires close attention and appropriate treatment. These conditions are so numerous and so different that it is impossible to state all that may be required to fulfil this intention. This is, however, the less necessary, as the circum-

stances under which tympanites occurs, and the pathological causes producing it, are duly considered, with the treatment required for each, in the articles on *Adynamic Fevers*, inflammations of the *intestines* and of other portions of the intestinal tube, *hysterical affections*, *colic*, *ulcus*, and on other disorders upon which tympania is often contingent. The diverse sources of this affection, and the very opposite pathological states which may occasion it, sufficiently explain the success which has sometimes followed very different or even opposite indications and means of cure. Thus, when depending upon inflammatory action, the antiphlogistic treatment and regimen, as advised by J. P. FRANK and others, are then required; but when depending upon a paralyzed state of the intestines, consequent upon either organic lesion in some part of the digestive tube, or upon a morbid condition of the blood, as in the advanced stage of low or malignant fevers, then stimulants, tonics, carminatives, and restoratives, as turpentine, camphor, musk, ammoniacum, asafetida, galbanum, capsicum, myrrh, rue, &c., are equally necessary. In these latter circumstances, and especially when the bowels are loaded by offensive sordes or morbid excretions, then powdered charcoal, as advised by FRANK, and employed by myself in such cases, in conjunction with antiseptics or other means, or with one or more of those just named, may be employed. The carbon may be administered in doses of half a drachm to a drachm, twice or thrice daily, in the state of powder, in any suitable vehicle. In the case of a very celebrated general, attended some years ago by Dr. F. HAWKINS and myself, this substance was administered in that quantity and even in more frequent doses, and was conjoined with active medicines; it having been adopted chiefly for the removal of the fetor characterizing the evacuations and tympania in the advanced stage of low fever. For inflation of the bowels in the last stage of fevers, in dysentery, in chronic diarrhœa, in misplaced gout, &c., the treatment already advised (§ 17) is often beneficial; and in many of these, especially in aged subjects, charcoal is often of use, and seldom fails of removing the fetor characterizing these cases.

[When chronic, or owing to atony of the muscular coat, *electricity* by the electro-magnetic apparatus has often been found useful. We have known also the *galvanic belt* worn round the body to afford much relief, and exert a curative action. Cold applications to the abdomen, the various preparations of iron, sea-bathing, horse-back exercise, a firm band about the abdomen, all may prove advantageous in cases where these remedies are indicated. *Articles of food* prone to fermentation, or the extrication of large quantities of air, must be avoided, such as *peas*, *beans*, *turnips*, *greens*; also fermented liquors, sweet wines, pastry, &c. The bulk of a meal should be small, and condiments used, as pepper, mustard, &c.]

URINARY BLADDER.—*SYNON.*—*Vesica Urinaria*; *Vesica urinialis*; κύστις, *Cystis*; *Urocystis*; —*Vesica*; — *Vessie*, Fr. *Harnblase*, Germ.

1. The urinary bladder is a musculo-membranous reservoir for the reception of the urine, until the accumulation of a certain quantity solicits the discharge of this secretion. This reservoir is situated in the hypogastric region, between the pubes and rectum in man, and between the pubes and vagina in the female. Its several connexions with the urinary and sexual passages, in both sexes, and its other anatomical relations, need not be noticed at this place. It is sufficient that we bear in recollection that, in addition to the disorders and lesions which are seated in it solely or chiefly, it is liable, in consequence of these connexions, and of the nervous and vascular communications existing between it and other parts, to several sympathetic affections, the most important of which are those depending upon lesions of the kidneys and ureters, and upon those of the prostate gland and urethra. In all cases, therefore, when the urinary bladder appears to be the seat of disease, our attention should be directed also to the states of these organs and passages; and not be limited to these, but be extended even farther, and more especially to the composition and condition of the urine and of its deposits, with the several relations of digestion and assimilation.

2. I. IRRITABILITY OF THE BLADDER.—CLASSIF.—II. CLASS, III. Order. (*See Preface*.)

3. DEFINIT.—*A frequent and urgent desire to micturate, independently of febrile symptoms and of inflammation, and of organic lesion of the urinary bladder and prostate gland.*

4. i. SYMPTOMS.—A person otherwise in good health feels an urgent desire to void his urine after very short intervals, and if the desire be not gratified, either he is incapable of retaining it, or he retains it with great difficulty, and with more or less pain. The effort at micturition is sometimes attended by pain in the glans or under the frænum, and by straining; and although the

calls are frequent, the quantity passed at each call is very small. These latter symptoms are most frequent in old or aged persons, and in those who have been addicted to masturbation or sexual excesses, in whom the prostate is more or less tumid or enlarged. Hysterical persons are often liable to this disorder; but in these the urine is more copious and pale, and contains less than the usual proportion of solid ingredients, the nature of which are not altered. When irritability of the bladder has continued long—the organ having for a long period ceased to be distended by the accumulation of urine—the capacity of it becomes permanently accommodated to the paucity of its contents, and incapable of containing more than two or three ounces.

5. Mr. COULSON, in his admirable work on Diseases of the Bladder and Prostate Gland, remarks that, notwithstanding this contracted state, if there be no stricture or disease of the prostate, the parietes of the bladder are often thinner than natural; and that it would seem that protracted irritation produces absorption of part of the substance of the organ. Opportunities of examining after death the bladder of persons who laboured under this affection in its idiopathic form are very rare. Mr COULSON examined the body of a gentleman of a very nervous temperament, long a sufferer from this disorder, who was carried off by disease of the lungs; but he could not detect the least alteration in the appearance or structure of the bladder, or of any of the urinary organs.

6. ii. THE CAUSES of this disorder require recognition in each case which comes under treatment. Old persons, or the aged, and next the very young, are more liable to irritability of the bladder than youths or the middle-aged; but the causes producing it in the aged are generally very different from those occasioning it in children. The nervous temperament, weak, irritable and anxious dispositions, and gouty and rheumatic persons are most predisposed to it. Those subject to chronic dyspepsia, to nervous giddiness, tremors, or to sealy eruptions, are often also afflicted with this complaint.

When it occurs in females it is sometimes referable to injury from pressure, either during pregnancy or in parturition, or to disorders or lesions of the uterus, ovaria, or vagina. It may be occasioned in both sexes by hæmorrhoids or irritation of the rectum by ascarides, or by chronic states of dysentery. It may occur, in a slight form, even independently of hysteria, in males as well as in females, from self-pollution, or from irritation of the spinal nerves increasing the organic sensibility of the bladder.

7. a. The most frequent causes are probably those which are referable to the *states of the urine*, arising either from the nature of the ingesta, or from the changes consequent upon primary or secondary assimilation. It has been well remarked by Dr. PROUT, in his celebrated work, that cases of irritable bladder, depending on functional derangement of the kidneys, usually result from the unnatural properties of the urine. All deviations from the normal condition of the urine, whether in deficiency, or in excess, or in kind, are recognised by the containing organs, and may prove a source of irritation in the bladder. "Hence, whenever the urine is very dilute or very concentrated, or is preternaturally acid or alkaline, or contains any unnatural ingredient, the urinary organs in general, and the bladder in particular,

though perfectly healthy, are liable to become excited and irritable, and the individual has no peace until the unnatural secretion is discharged. In such cases the fault lies, not in the bladder, but remotely in the kidneys and assimilating organs."—(*Op. cit.*, p. 366.)

8 The use of various fruits, ripe or unripe, especially by children, and even by adults, and disorders of digestion and of assimilation, occasioned by these or by other causes; the elimination from the blood of unwholesome substances, conveyed into it from the organs of digestion, whether subsequently altered or unaltered by the kidneys; the excessive use of alkalis, or of these combined with the vegetable acids, and alkaline states of the urine from these or other causes; and the prolonged use of acids, or of the nitrate of potass, or of the oxide of potassium, or of other diuretics, may severally occasion this complaint.

9. *b.* The irritation of ascarides in the rectum, and morbid states of the urine, caused either by unwholesome food, by unripe fruit, or by impaired assimilation, or by spinal affections, or by rickets, are the most common causes of this affection in children. Mr. COULSON met with cases in children which were caused by so great a contraction of the orifice of the prepuce as hardly to admit the point of a probe; circumcision cured the complaint. When irritability of the bladder occurs in this class of patients about the periods of dentition, it may generally be imputed to disorder of the digestive organs, and to consecutive alterations of the urine. The connexion of irritability with paralysis of the bladder is not unfrequently met with in children (§ 36).

10. *c.* *Symptomatic irritability* of the bladder is much more common than the idiopathic disease. Granular and other organic lesions of the kidneys are generally attended, especially during the night, with frequent and urgent desire to evacuate urine, this excretion being always more or less morbid even from an early period. Diseases of the prostate gland and of its vicinity, organic, inflammatory, or malignant very generally, and strictures of the urethra not unfrequently, are accompanied with this complaint. Indeed, strictly speaking, irritability of the bladder is merely symptomatic, either of disease of some adjoining or some closely related organ, or of morbid conditions of the urine; and this may be the case even in those considered purely nervous, or most devoid of manifest structural change.

[*Gonorrhœa* and *masturbation* are among the most frequent causes of irritability of the bladder, the irritation being transferred from the urethra to the neck of the bladder; causing frequent micturition, with tenesmus, pain, bloody urine, &c. All the stimulating class of diuretics may cause the same difficulty; also those resinous cathartics, like *aloes*, which act on the lower portion of the intestinal canal. Turpentine, cantharides, and nitrate of potass are the most likely, perhaps, of the diuretics, to irritate the bladder.]

11. *iii.* THE DIAGNOSIS of this complaint is often of importance; and nothing tends more to determine this than a careful examination of the urine. Irritability of the bladder will not be mistaken for *diabetes*, if the quantity and quality of the urine be ascertained. Although irritability is a symptom of inflammation of this viscus, yet it is necessary to ascertain its independence of inflammatory action; and this is to be inferred chiefly from the absence of those local and con-

stitutional symptoms characterizing cystitis, either in an acute or chronic form. The absence of pain in the region of the bladder, and of frequency of pulse or of other febrile symptoms, especially towards evening, will indicate the independence of the recent state of the complaint of acute inflammation; while the more chronic state of irritability will not be imputed to chronic inflammation of the bladder, if the constitutional powers of the patient be not very sensibly impaired by it. The dependence of the complaint upon disease of the prostate gland may readily be ascertained by an examination *per rectum*. Not only, however, may there be irritability, but also pain of the bladder, without any manifest disease of this viscus; the mischief being confined to the kidneys, chiefly in the form of calculi of these organs. Instances of this kind are adduced by MORGAGNI, PROUT, COULSON, H. J. JOHNSON, and others, and have come under my own observation. Dr. PROUT remarks that, in certain renal affections in particular habits, even where the urine is not very unnatural, the pain is confined chiefly to the neck of the bladder; but where the urine is actually diseased, and especially when it is alkaline, we may be certain that the kidney is functionally, and if the patient be of a scrofulous habit, and the case of long standing, very probably organically affected.\*

12. *iv.* TREATMENT — *a.* In recent cases, the states of the general health and of the urine will frequently indicate a successful treatment. When the urine is very acid, or scanty, or furnishes a red sandy deposit, and when the complaint appears in connexion with either gout or rheumatism, then bicarbonate of potash may be given, with or without the nitrate of potash, in tonic or bitter infusions or decoctions; the carbonates of soda and of ammonia being inappropriate, the former owing to its favouring the formation of urate of soda, the latter to its influence in generating urea and uric acid. Mr. COULSON states that great relief will sometimes be obtained from cupping on the perineum. This will be more especially the case if any congestion of, or vascular determination to, the prostate gland be present. Liquor potassæ, prescribed in bitter infusions, with henbane or opium, or with small doses of colchicum, in the gouty or rheumatic diathesis, is also of great service. Where the potash, in either of the states now mentioned, is not productive of relief, magnesia may be given so as to preserve the bowels in an open state, an occasional dose of equal parts of the compound infusions of gentian and senna being also taken.

13. *b.* In cases which manifest a nervous character, or which seem to be results of abuse of the sexual organs, tonics are especially required, either in combinations already mentioned, or with the mineral acids; as the infusion or decoction of *cinchona* with the nitro-muriatic acids, and with henbane or opium, or with a few drops of tincture of opium, or with the compound tincture

[\* This disease has sometimes been mistaken for stone in the bladder. We have known two instances where the operation of lithotomy has been performed without finding any calculus in the bladder. Dr. GROSS relates a case of a boy four years of age, who had a constant desire to micturate, complained of severe pain in the urethra and neck of the bladder, pulled constantly at the prepuce, and strained violently whenever he voided his urine, which was occasionally tinged with blood. On sounding, no stone could be found, and he was cured with alterative doses of calomel and rhubarb, with carb. soda, and in the intervals quinine and Fowler's solution.]

of camphor. The mineral acids may also be given with the decoction of *pareira brava*, or of *uva ursi*, or with the infusion of *buchu*, and with the additions just mentioned. I have prescribed the tincture of the muriate of iron in *calumba* or *quassia*, and *anodynes*, with benefit, for cases of this kind. Mr. COULSON remarks that the decoction of *uva ursi* and the infusion of wild carrot seeds will occasionally give great relief; but that no medicine is so generally successful in irritability of the bladder as the infusion of *diosma*; and he adds that, from time immemorial, the *buchu* leaves have been held in great esteem by the natives of the Cape of Good Hope as a remedy for irritative and inflammatory affections of the urethra, bladder, prostate gland, and rectum, and also for rheumatism, indigestion, and gravel. The natives of the Cape and the Dutch are partial to the spirit of *buchu*, made by distilling the leaves in the dregs of wine, and call this spirit *buchu brandy*; and they use it for all chronic diseases of the stomach and bladder, especially colic, spasms, &c.\* A tincture of *buchu* is ordered by the Edinburgh and Dublin Colleges; and half a drachm to a drachm of it may be given for a dose. In these and similar cases of irritability an opiate suppository, or a starch enema containing from one to two drachms of sirup of poppies, or about thirty drops of tincture of opium, may be administered at night; or a pill with opium, or henbane, and extract of colchicum, shortly before bed-time.

[Dr. GROSS (*loc. cit.*) speaks favourably of the *tinct. of cantharides* in this disorder, and states that he has used it with marked advantage in several cases during the last few years, especially in the irritation of the bladder in young children and hysterical girls, when carried to the extent of producing slight strangury. *Haerlem oil* has sometimes succeeded when every thing else has failed, in doses of from 10 to 20 drops. The saturated tinct. of the *Phytolacca decandra* was often prescribed in this disease by the late Dr. PUYSC, in doses of two drachms every 7 or 8 hours. The decoction of *soot*,  $\zeta\text{ij}$ . to one lb water, and filtered, is highly recommended by Dr. GIBBON (*Bull. l'Acad. de Méd.*, March, 1837).]

14. *c.* When this complaint is *symptomatic* of granular or other organic disease of the KIDNEYS, or of enlargement or other lesions of the PROSTATE GLAND (see those articles), then the treatment must be based on the primary and chief malady. When it is connected with the gouty or rheumatic diathesis, or with either of the scaly eruptions, then the bicarbonate of potash, or the solution of potash, and small doses of the iodide of potassium, in equal parts of the compound tincture of cinchona and of the fluid extract of *sarsaparilla*, with one of the narcotics already mentioned, are often beneficial. If the urine becomes alkaline, or if the iodide appear to perpetuate the irritability, the alkali and the iodide should be relinquished. In this state of the disease, colchicum may be conjoined with the above, or even a small quantity of opium may be added to them. In most cases, especially when the nightly rest of the patient is much disturbed, an opiate in some suitable form should be given in the evening or at bed-time.

15. *d.* When the complaint occurs in *hysterical females*, or in connexion with the accession, or with disorder of the catamenia, the prepara-

tions of iron, or of valerian, or of *asafœtida*, or of aloes, the bowels being acted upon by preparations of the latter, are generally beneficial. In these cases also, the tincture of *sumbul*, in doses of twenty to forty drops, with five or six of the tincture of opium, is often of service.

16. *e.* The incontinence of urine often afflicting children, and generally during sleep, seems to proceed from an association of irritability with partial paralysis of the bladder, or at least with impaired tonicity of the sphincter vesicæ. In most of these cases the general health, the digestive functions, and the state of the urine are more or less disordered; and to these especially medical treatment ought to be prescribed. In many instances, while due means are employed for these, stimulating liniments rubbed along the spine, or sponging the back and sacrum with a strong solution of salt night and morning, will prove of service. (*See also* § 39.)

17. *f.* In all cases of irritable bladder the *diet* and *regimen* of the patient should be duly regulated, and with especial regard to the states of the digestive functions, of the urine, and of the organs most intimately related to the offices of the bladder. Fruit and vegetables are often injurious. Much animal food is even more hurtful, especially in the gouty, rheumatic, and uric acid diathesis. Malt liquors and spirits are still more injurious, and wine is very rarely of service. Sexual excesses ought also to be avoided, and sexual intercourse seldom indulged in. The calls to micturate should be deferred as long as possible, and the mind be diverted from it; for a constant response to each early call ultimately gives rise to a habit which increases and becomes confirmed from the want of opposition to it.

[*Neuralgia of the bladder* may be noticed with propriety under this head. This is a painful affection of the organ, generally referred to the neck of the bladder, occurring in paroxysms daily, or every other day, at about the same period of time. It is met with most frequently in miasmatic districts, and in hysterical subjects, though by no means confined to females. For the most part it occurs in the old or middle-aged. The attack is generally preceded by a sense of uneasiness in the perineal region, with occasional numbness, aching, or a sharp, tingling pain; and these symptoms, with remissions, may last several days, the attacks becoming more distinctly paroxysmal; the paroxysms lasting from two to six hours, and the pain resembling that produced by a fit of the stone. Dr. GROSS represents the pain as extending to the neighbouring organs, as the rectum and anus, the urethra and inside of the thighs. In the female the *uterus* is sometimes involved, and the spermatic cords in the male. The pain is generally very severe in the sacral and lumbar regions in both sexes. The desire to micturate frequently is strongly marked, although attended with difficulty; and a sensation of heat and burning is felt along the urethra, but especially at the extremity of the penis, from whence it frequently extends to the neighbouring parts. "The paroxysm," says Dr. GROSS, to whom we are indebted for this description, "generally goes off gradually, leaving no other inconvenience than a sense of soreness, or aching in the neck of the bladder, perineum, and posterior part of the urethra. During the intermissions the urine is voided without difficulty, and the patient feels comparatively comfortable, almost as

\* The fluid extract is far preferable to the tincture. Tilden's preparations are altogether reliable.]

well, indeed, as if he had not suffered any pain. When the attacks assume the quotidian type, they usually occur in the evening, during the night, or early in the morning. Occasionally they make their appearance soon after eating, and in a few instances they occur twice in the 24 hours; thus leaving the poor sufferer scarcely a moment free from pain.\*

This affection is rarely accompanied with fever. There is usually much derangement of the digestive organs, with torpidity of the bowels; the sleep is disturbed, the pulse quick and irritable, the extremities cold, and the general health greatly impaired. In severe and obstinate cases there is a gleet discharge from the bladder, with soreness in the perineum and hypogastric region, and a sense of coldness, with numbness, in the neighbouring parts. The urine is generally normal in quantity and quality, except in gouty or rheumatic subjects, in whom it is generally acid, scanty, and mixed with red sand.

The *diagnosis* of this affection is not always easy, as its paroxysms closely resemble those produced by calculus in the bladder. Dr. Gross advises sounding the bladder. The most important signs are the sharp and darting pains, the paroxysmal character of the disease, the itching and scalding in micturition, the attempts at which are frequent, urgent, and difficult, and the numbness in the perineum, scrotum, groins, and thighs.

The *causes* are obscure, though they are probably the same as excite neuralgia in other parts. No doubt, masturbation, venereal excesses, stricture of the urethra, stone in the bladder, piles, uterine diseases, may excite it in nervous, irritable subjects; and malaria, indigestion, the depressing passions, and a morbid state of the urine, may act as predisposing, if not exciting causes. Its seat is supposed to be, as in other cases of neuralgia, in the nerves of the part, though dissection has thrown no light on this point. The *prognosis* of vesical neuralgia must be guarded. Though it seldom, perhaps, terminates fatally, yet it is apt to prove obstinate in spite of the most judicious management. Sometimes it disappears suddenly, like other neuralgias, but more frequently it persists for years, undermining the health, and terminating in serious organic mischief. The treatment of this affection must be regulated by the predisposing and exciting causes, if ascertainable. In miasmatic regions, the usual antiperiodics, quinine, Fowler's solution, &c., promise best. If inflammatory symptoms be present, they are to be combated by the usual antiphlogistics. Dr. Gross recommends early, copious, *general blood-letting*, repeating it every day or two till the force of the attack is abated, and this to be followed by leeches to the perineum, or over the seat of the pain. *Purgatives* are also advised, especially if the affection is of miasmatic origin, trusting to those which produce free evacuations, but avoiding drastics. Mercurials are useful adjuncts, but salivation is to be avoided. "I am convinced," says Dr. Gross, "that a systematic course of purgation is not only unequivocally beneficial, but absolutely indispensable to a speedy and permanent cure."

The preparations of *iron* will sometimes prove useful, but they are inferior to *quinine* and *arsenic* in this affection. These, as well as *strychnine* and *aconite*, with opium, are recommended by

Dr. Gross in pill, according to the following formula:

R Acid. Arseniosi, gr. ij.; Strychninæ, gr. j.; Ext. Aconiti, gr. viij.; Pulv. Opii, gr. v. M. ft. 16 pills. One pill to be taken every 6 hours.

If opium disagrees, *lupuline* or *hyoscyamus* may be substituted for it. If nausea results, the dose is to be diminished, or the pills taken less frequently. It is also advised not to continue the pills longer than a week or ten days at a time, resuming them in the course of two or three days. Under this course the disease is often cured; and the same combination will prove useful in other forms of neuralgia. To relieve the violent pain of the paroxysms, *narcotics*, in full doses, are necessary; of which the salts of *morphia* will prove among the best. We have found *stramonium*, in the form of *Tilden's fluid extract*, very efficacious in every form of neuralgia. It is to be given in large doses, and the system kept under its influence for some time. *Belladonna suppositories* are also worthy of a trial, if other means fail. When the disease occurs in a malarious district, and is associated with hepatic or gastric derangement, an emetic will often arrest or cut short the paroxysm. The wine of *colchicum*, with *morphia*, at bed-time, will be beneficial, especially in rheumatic or gouty subjects, alternated with mercurial purgatives. If there be acidity of stomach or flatulence, a combination of bicarbonates of soda and potash may be advantageously given, or an occasional dose of calcined magnesia.

Dr. Gross condemns the use of *bougies* in vesical neuralgia, as advised by M. CIVIALE (*Gazette Medicale*, July, 1836), after considerable experience in their use. He thinks more favourably of injections of acetate of lead and opium, or of a watery solution of opium and hyoscyamus, employed tepid, cool, or cold, as is most agreeable to the patient. If the disease prove very intractable, then *counter-irritation* to the perineum, the supra-pubic region, the sacrum, the upper and inner parts of the thighs, by the moxa or Vienna paste, will be advisable. When the disease depends on piles, stricture of the urethra, foreign bodies in the bladder, &c., the treatment must be directed to the removal of the original cause, which is always to be assiduously sought for, else it may be overlooked by the practitioner. The *warm bath* is an important remedy in every form of the disease. But, as in all other diseases, although our remedies be carefully selected and judiciously applied, yet without strict attention to *diet* a cure can not be expected. All kinds of alcoholic liquor must be sedulously avoided, as well as accecent fruits and vegetables, new bread, strong coffee, cheese, &c. The digestive organs must be strengthened, and all the usual hygienic appliances faithfully carried out. If the patient reside in a malarious region, a change to a more healthy district will be useful.]

18. II. SPASM OF THE BLADDER.—CLASSIF.—II. CLASS, III. ORDER. (*See Preface*.)

19. DEFINIT.—A sudden and violent attack of pain in the region of the bladder, extending along the urethra to the glans, with either involuntary expulsion or retention of the urine.

20. A. This disorder is most commonly *symptomatic* either of stone in the bladder or of gonorrhœa, especially when this latter is treated by injections; or of organic disease of the kidneys, or of parts adjoining the bladder. Dr. PROUT remarks that it may be caused by acid urine, by

\* "On Diseases of the Urinary Bladder," &c. Phil., 1835, p. 264.

abscess of the kidney, by ulceration or other disease of the prostate gland, bladder, &c., or by retention of urine, or by gout, or by venereal excesses. Irritating diuretics, cantharides taken internally, the application of blisters, hysteria, masturbation, the irritation of ascarides in the rectum, dysentery, or tenesmus, may severally excite an attack. When it is connected with gonorrhœa or the treatment of it, then the sphincter vesicæ is thereby either irritated or inflamed, and spasm supervenes as soon as urine passes into the bladder.

21. *B.* The sudden and violent attack of pain in this viscus, *characterizing* this complaint, is attended by a constant desire to void urine, without the ability to do so, and the agony felt during these attacks is excessive. The contraction of the bladder excites the muscular coats of the rectum, and occasions also a desire to evacuate the bowels, or more or less tenesmus. Mr. COULSON remarks that the closure of the ureters at their vesical extremities has given rise to dilatation of these ducts and of the pelvises of the kidneys, and to serious changes in the kidneys; and that, after an attack of spasm, from which the patient has apparently recovered, it sometimes happens that a new train of symptoms appears, indicating the injury which the tubular and secreting structure of the kidneys has received. Frequent attacks of spasm also sometimes injure the tone and contractility of the bladder so much as ultimately to induce a partial or more complete paralysis of the organ (§ 27).

22. *C.* The *diagnosis* of spasm of the bladder is not difficult; it may, however, be confounded with inflammation; but in this latter the pain is constant, commences with uneasiness, and gradually becomes more and more severe. Spasm occurs suddenly; the pain is violent and constrictive; whereas in inflammation the pain, when greatest, is either lancinating or throbbing, and is attended by more or less febrile action, of which the former is generally exempt. In both the urine is usually retained, or passed in the latter in very small quantities, and after remarkably short intervals. Spasm may, however, be associated with inflammation of the mucous coat of the bladder, as spasm of the coats of the colon is associated with inflammation of the mucous coat of the intestine. In such cases the spasm is only a symptom aggravating the character of the inflammation, febrile symptoms more or less manifestly attending this latter.

23. *D.* The *treatment* of spasm of the bladder will appear from the above to depend chiefly upon the pathological state occasioning it. If it be consequent upon inflammatory action, either of the sphincter vesicæ, upon suppressed gonorrhœal discharge, upon the use of irritating injections, or upon inflammation of the bladder, *bleeding*, according to the grade of morbid action and habit of body of the patient, should be prescribed, either by venæsection, cupping, or by leeches, and be repeated if required. The warm bath, fomentations, cooling aperients, and diaphoretics should follow vascular depletion; and demulcents with anodynes, emollient enemata with anodynes or narcotics, &c., should also be prescribed. If the complaint supervene on gonorrhœa or the use of injections, the above treatment is appropriate; local bleeding, however, generally proving sufficient.

24. If spasm of the bladder occur in the gouty diathesis, or upon the suppression of a paroxysm of gout, or as misplaced gout, the regular form of the disease should be solicited by means of mustard pediluvia, and mustard poultices to the feet, while the soothing and anodyne remedies above mentioned are exhibited. In cases of this kind, as well as in many others, magnesia and sulphur may be taken, with small doses of colchicum, of camphor, and of opium; and if the former be given in decided doses, so as to act upon the bowels, a more rapid effect will be produced upon the spasm than by any other means. If the state of the urine occasion or aggravate the spasm, appropriate means should be used to correct this state.

25. When the disease is symptomatic of a calculus in the bladder, or in the kidney, or passing the ureter, the warm bath, fomentations, demulcents, emollients, and narcotics, or anodynes, taken by the mouth and administered in enemata, are generally of service; but when the calculus is in the bladder, these means are only of temporary benefit—permanent relief must be looked for only from the surgeon. Cases of spasm affecting chiefly the sphincter vesicæ, and causing retention of urine, are generally symptomatic of irritation or of disease of adjoining parts, and are relieved by the *tinctura ferri sesquichloridi* taken in doses of ten to twenty drops in water every quarter of an hour, or by a suppository containing the extract of belladonna, or by a belladonna plaster applied over the perineum, while the emollients and anodynes already advised are taken internally. Mr. COULSON recommends a poultice containing powdered camphor to be applied over the perineum, or a liniment composed of camphor and opium; and states that emollient clysters containing some of the watery extract of opium often afford instant relief.

26. III. PARALYSIS OF THE BLADDER.—CLASSIFICATION.—I. CLASS, II. ORDER. (See Preface.)

27. DEFINITION.—*Partial or complete loss of the contractile power, and of the organic sensibility, of the bladder; often also with loss of power of the abdominal muscles, whereby the urine is partially or completely retained.*

28. *i.* HISTORY.—Paralysis of the bladder, whether partial or complete, whether temporary or permanent, depends on loss of power, either originating in the organ itself, or affecting it consecutively upon injury or disease of the spinal chord, or of the brain, or of their membranes.—*a.* A *partial* form of paralysis sometimes occurs as a symptom of extreme debility or exhaustion in the course of acute or chronic maladies, as of typhoid or adynamic fevers, of hectic, and of the last stage of organic diseases. In these circumstances, the contractility and organic sensibility of the bladder is more or less impaired, and the power of the abdominal muscles to aid by their contraction the expulsive efforts of the detrusor urinæ, is equally lost.

29. *b.* In some cases the loss of power in both is *general and complete*, and this state of the disease, especially in its advanced or protracted form, may be attended by a constant dribbling of the urine, owing to the over-distention of the bladder having overcome the resistance of the neck or sphincter vesicæ. Thus incontinence of urine is superadded to retention, and the latter is sometimes mistaken for the former. In such cases examination of the abdomen and region of

the bladder, or the introduction of a catheter, will disclose the state of matters; and strict attention should be paid to the excreting functions of the urinary organs in all fevers and constitutional maladies.

30. *c.* Paralysis of the bladder, giving rise to retention, may come on gradually, especially in advanced age; either in consequence of disease of the kidneys, or of the prostate or urethra, or after a prolonged neglect of evacuating the bladder or the suppression of the desire to evacuate. In these circumstances, however, the paralysis and the retention may be at once complete. Although this form of the affection is most frequent in aged persons suffering from disease of some other parts of the urinary apparatus, yet it may also affect the middle-aged, especially when the desire of evacuation has been long suppressed; the consequent over-distention having overcome the power of contraction, the abdominal muscles either failing to expel the urine, or expelling it only partially. In these and similar circumstances a frequent desire to micturate occurs, and after expulsive efforts made by the abdominal muscles a small quantity only is expelled; and this state may be mistaken for a form of irritability of the bladder; but upon a strict examination of the abdomen, or upon the introduction of a catheter, a large accumulation of urine is found in the viscus.

31. In some persons even of middle age, a more or less manifest state of paralysis is consequent upon impaired health caused by anxiety, fatigue, excessive application to business, and neglect of calls to micturate, or by venereal excesses or masturbation. When these latter causes have existed, a state of complete or incomplete *tubes dorsalis* supervenes, with manifest weakness of the loins and lower limbs; and if relief be not obtained, paraplegia, with complete paralysis of the bladder, ultimately results. In both this and the immediately preceding cases, as well as in some others, the over-distention of the bladder, or the distention of it to a certain extent, occasions a frequent desire or effort to evacuate the urine, and a small quantity only is passed, the power of contracting farther being lost, or the contractions of the abdominal muscles being sufficient only to expel that small quantity. In such cases the catheter is often required.

32. *d.* *Injuries and diseases of the spinal cord and brain, and their membranes,* occasion the most complete and severe instances of paralysis of the bladder; more especially lesions seated in the spinal cord or its membranes, and whether in the cervical, dorsal, or lumbar regions. In this class of cases the effects produced upon the bladder and upon the state of the urine are different, or vary more or less with the amount of injury or disease, or with the rapidity of progress of the latter in the nervous centres; but they are generally remarkable according to the severity or danger of either. At first, or immediately after the occurrence of these, the urine may be more or less acid and free from mucus; but especially after injury of the spinal cord it soon becomes alkaline, turbid, and ammoniacal, evincing this state at its discharge; and when it cools it deposits much adhesive mucus. After a short time phosphate of lime is found in the mucus, which afterward is sometimes blended with blood. The urine collected in the bladder is altered, either during the process of secretion or during its re-

tention in the bladder, and is generally changed in the following manner: The urea is converted into carbonate of ammonia, which irritates the mucous surface of the bladder, and causes the exudation of much viscid mucus. The neutral triple phosphate of magnesia and ammonia contained in the secretion forms prismatic crystals, and presents different degrees of transparency. The inflammation of the bladder consequent upon paralysis of the bladder, caused either by injuries or disease of the nervous centres, extends from the mucous to the other coats of the organ, if the patient live for some time; and the parietes become thickened and incapable of contraction; the urine requiring to be drawn off, and always presenting a fetid and alkaline character. The question in these cases is whether the change in the urine is owing to the altered nervous power of the kidneys, or is it the result of retention in the bladder? From some attention which I have paid to this question, I conclude that the change in the urine takes place primarily and chiefly in the kidneys, owing to the loss of that portion of nervous power which the spinal nerves convey to the renal ganglia; and that it is increased during the retention of the urine in the bladder, the paralyzed state rendering this viscus more prone to inflammation, and to the more rapid supervention and progress of the changes consequent upon inflammation.

33. As this state of disease proceeds, the pain or uneasiness of the neck of the bladder and glans penis at first experienced subside and ultimately disappear, although distention may continue or increase. The desire to pass urine is not expressed; and while the local symptoms subside the constitutional become aggravated. The pulse is much accelerated, thirst is increased, and restlessness and anxiety of mind are augmented. The fur on the tongue is thicker, deeper, and darker-coloured. Delirium supervenes, with a urinous odour of the perspiration, and stupor or profound coma supervenes, and the patient dies in this state; the complaint being, perhaps, mistaken for typhus fever, if due attention have not been directed to the states of the urinary functions and bladder. Patients, especially those advanced in life, when attacked by fever, owing to the congested states of the nervous centres, may experience similar changes in the urine, and a similar paralysis of the bladder; and if this unfavourable complication of fever be overlooked, it rarely fails of being the chief cause of a fatal issue.

34. Paralysis of the bladder occurs chiefly in the aged; and although in them, as well as in some younger persons, it may be favoured or caused by the states of the spinal cord or of its membranes, it is most frequently consequent upon disease of the prostate gland or neck of the bladder, or of the urethra, causing over-distention of the organ. When this complaint affects females, especially from puberty to the decline of life, it is generally connected with *hysteria*, or with the advanced stage of spinal congestion (hysterical paraplegia) caused by uterine irritation. I have seen several cases of hysterical paraplegia where a surgeon was required to draw off the urine, the complaint having been imputed to masturbation. When it occurs in married females, it may be either a symptom of pregnancy, or of injury experienced during labour or delivery. In the fourth month of pregnancy, or about that time, or near the period of confine-

ment, retention of urine may occur, and if it be neglected, a paralyzed state of the bladder may supervene from distention. Similar results may follow retroversion or anteversion, or prolapsus of the uterus. Imperforate hymen, and obstructed catamenia from this cause have even occasioned this complaint.

35. *e. Hysterical paralysis* of the bladder is believed by Sir B. C. BRODIE, and very justly, in many cases, to be owing to defective efforts of volition. He remarks that, in the first instance, it is not that the nerves are rendered incapable of conveying the stimulus of volition, but that the effort of volition is itself wanting; and this corresponds with what is observed in other affections connected with hysteria. "As the distention increases the patient begins to be uneasy, and at last suffers actual pain, and as soon as this happens volition is exercised as usual, and the bladder begins to expel its contents." If not relieved by means of the catheter, the hysterical retention of urine is thus of short duration; but if the catheter be had recourse to, the natural cure is prevented, and the disease may be indefinitely prolonged. "The general rule," Sir B. BRODIE adds, "in the treatment of these cases, is to interfere but little;" but this rule is not without exceptions, for, in a few cases where the bladder has been very much distended, it loses its power of contraction, and even though the patient endeavours to micturate, no water flows. Under these circumstances artificial aid should be obtained.

36. *f. The affection* which sometimes occurs in children, especially in delicate boys, and which is characterized by the discharge of urine during sleep, has been variously explained; by some it has been imputed to irritability of the bladder, by others to a morbid state of the urine, causing irritation of this viscus, and by some to paralysis of the neck of the bladder, occurring during sleep. That this last condition may obtain is not unlikely, as the affection is not unfrequently associated with prolapsus of the rectum after a motion, and with deficient tonic contraction of the sphincter ani. It may, however, depend, in different cases, upon the association of all these morbid conditions in different degrees, the share that a morbid state of the urine may have in its production being ascertained by the examination of this excretion.

37. *ii THE TREATMENT* of paralysis of the bladder is, 1st, *constitutional*, and, 2d, *local*; but in many cases the latter should precede the former, especially as respects the urgent necessity of obtaining immediate relief. As to the best means of attaining this end I must refer to surgical writers, and especially to the able and precise instructions of Mr COULSON, in his work on the "*Diseases of the Bladder*," &c.—*A. The constitutional treatment* must chiefly depend upon the nature of individual cases, upon the pathological conditions occasioning this disease; but in most cases, and particularly in old cases, medical treatment is of little avail; surgical appliances, especially frequent introductions of the catheter, being required during the life of the patient. Trial, however, may be made of strychnine, gradually increasing the dose, and carefully observing its effects on the nervous and muscular systems. I have generally preferred the extract of *nux vomica*, in doses of a quarter of a grain, gradually increased to one grain, given twice or thrice daily, and combined with the aloes and myrrh pill, and

purified extract of ox-gall, or with the compound galbanum pill. I have also prescribed terebinthinate embrocations or epithems, to be applied over the loins and sacrum. In the great majority of cases, and especially in aged persons, serious lesions supervene in the kidneys and in the pelvis of these organs, and thus complicate and farther aggravate the disease, and render recovery altogether hopeless.

38. *B. Hysterical paralysis* of the bladder is not unfrequently caused by masturbation, and a moral discipline is required, although it may not prudently be either suggested or enforced, unless with the utmost discretion. Indulgence and sympathy, on the part either of friends or of the physician, should be withheld, and the most nauseous anti-hysterical medicines should be exhibited, especially asafetida, turpentine, &c., both by the mouth and in enemata. In a case where this affection was rather simulated or feigned than actually present, I recommended, in the hearing of the patient, the actual cautery to be applied to the sacrum; but the complaint vanished soon after mention was made of the remedy, and directions given as to its employment.

39. *C. The paralyzed or relaxed state* of the neck of the bladder in children, noticed above (§ 36), generally disappears as the constitutional powers of the patient improve. I have found tonics, stomacheic aperients, chalybeates, and stimulating embrocations applied over the loins, the spine and sacrum being sponged every morning with a strong solution of salt, of great service. The patient should sleep on a hair mattress, covered with a water-proof cloth. Change of air, sea bathing, or sponging with sea or salt water, where the plunge-bath causes alarm, and exercise in the open air, are also beneficial, indeed are almost essential in these cases.

[The treatment of palsy of the bladder must of course, as in all cases, be regulated by its pathological cause, and the attending circumstances. The urine must first be drawn off, and care taken to keep the bladder emptied by using the catheter at stated intervals, as every four or six hours. This alone will often be all that is required to effect a cure. If the continued use of the instrument be required, the patient may be taught to introduce it for himself. In exceptional cases, the catheter may be allowed to remain in the bladder, removing it, however, sufficiently often to prevent any accumulations upon it. Dr. GROSS (*loc. cit.*) advises not to remove all the water at once, in cases of over-distention, for fear of severe depression on the removal of the stimulus of distention, as a fatal result may in this way be induced. This is good advice, and so is that of swathing the abdomen by a bandage, as after tapping in ascites.]

The use of the catheter should always be discontinued at the earliest possible period, and the patient should be urged, from time to time, to make propulsive efforts, so that the use of the instrument may be dispensed with; otherwise the bladder, becoming accustomed to its use, may lose entirely its contractile power.

The tone of the bladder must, in the next place, be restored, if possible; and this may be done by cathartics, where the paralysis is associated with paraplegia or great intestinal torpor. For this purpose calomel, with jalap or rhubarb, will be preferable. The cathartic may be repeated every other day, or, at first, every day, with

decided benefit. Dr. Gross states, also, that *emetics* are sometimes of signal benefit in this disease, especially when associated with derangement of the digestive organs and general torpor. Afterward, *strychnia*, *cantharides*, and *arnica* may be used with advantage, unless the affection be of an inflammatory form. These may be given in combination, one-sixteenth of a grain of *strychnia*, one-eighth of *cantharides*, and three to five grains *arnica*, in a pill, every six hours, watching closely the effects. We have used with great satisfaction the *extract of Ignatia Amara*, in this and other forms of palsy, in doses of one half to two thirds of a grain, three or four times a day. Dr. Gross recommends the *arnica* (forty to sixty drops of *tincture*), especially, in palsy of the bladder consequent on typhoid and other fevers, masturbation, and general exhaustion. The *ergot of rye* has been strongly recommended in this disease by Dr. ALLIER of France (*Jour. des Connaissances, Med. Chir.*, 1838), and Dr. DAY of London (*Treatise on the Diseases of advanced Age*), by whom it is preferred to *cantharides* and *arnica*. There can be no doubt that *ergot* exerts a specific action on the bladder as well as uterus, exciting the muscular contractility of both organs, and probably in an equal degree.

The *inflammatory* form of this affection must be treated strictly on antiphlogistic principles, viz., general and local bleeding, fomentations, warm baths, anodyne enemata, &c. When the disease occurs in the aged, or those debilitated by other diseases, *tonics* of the chalybeate class will prove beneficial. *Hysterical vesical palsy* is to be treated on the same general principles as other forms of hysteria. There can be no doubt that the disease is sometimes feigned, as many other diseases are, by hysterical subjects, for what object, often, it would be difficult to say, unless to gratify a morbid taste for notoriety, or to excite the sympathy of friends and relatives. *Asafœtida*, *valerian*, *musk*, *castor*, *iron*, and *morphia* may all be brought into play, and the patience of the practitioner well-nigh exhausted, before an acknowledged cure will be effected. Dr. Gross (*loc. cit.*) speaks highly, also, of a succession of *blisters* over the dorso-lumbar region, followed by an emollient poultice, and the surface sprinkled with one fourth of a grain of *strychnia*, after removal of the cuticle and adherent lymph, and repeated every twelve hours; and he remarks that "there is hardly any form of vesical paralysis, excepting, perhaps, the inflammatory, in which this mode of counter-irritation will not prove more or less advantageous." For farther details in regard to the treatment of this and other affections of the bladder, we refer to the above-quoted and most able work, *passim*.]

#### IV. INFLAMMATION OF THE URINARY BLADDER.

—SYNON.—*Cystitis* (from *Cystis*, a cyst or bladder), Sauvages, Vogel, Cullen, &c. *Inflammatio vesicæ*, Sennert, Hoffmann. *Cauma Cystitis*, Young. *Empresma Cystitis*, Good. *Uro-cystitis*, *Cystiphlogosis*; *Inflammation de la Vessie*, Fr. *Entzündung der harnblase, blasenentzündung*, Germ.

CLASSIF.—1. *Class*, 2. *Order* (Cullen). 3.

*Class*, 2. *Order* (Good). III CLASS, I.

ORDER (Author in Preface).

DEFINIT.—*A sense of pain in the region of the urinary bladder, increased on pressure, with a frequent desire to micturate, generally preceded by chills or rigors, and attended by inflammatory fever.*

40. i. STRUCTURES AND PARTS PRIMARILY OR CHIEFLY AFFECTED.—Inflammation of the bladder most frequently commences in the mucous coat, to which it may be limited, or it may extend to the external coats. When it thus commences it may be circumscribed, or it may affect all this coat. When the former obtains, the part covering the neck of the bladder and the cystic triangle is most commonly affected; but inflammation, whether limited to the mucous surface or affecting the other coats also, or even the whole parietes of the organ, generally commences in this situation, owing to the irritation of sabulous matter, of calculi, &c. The imperfect emptying of the bladder, especially in connexion with engorgement of the prostate, the contiguity of this part to the prostate and urethra, the liability of the extension of inflammation to it from these parts, and the participation in irritation of the rectum and vagina, also account for the more frequent commencement of cystitis in this part. From the extension of disease, cystitis may be consecutive upon inflammation of the rectum or vagina, upon metritis, and upon hæmorrhoids; and it is often consequent upon and complicated with inflammation of the prostate. In addition to these modes of commencement, cystitis may primarily attack the peritoneal covering of the fundus. This is comparatively a rare occurrence. The fundus of the organ is much less frequently the seat of the disease, particularly at an early stage, than the neck of the bladder and the parts situated posteriorly between the sphincter and entrance of the ducts. When inflammation commences in the peritoneal coat of the organ it usually arises from the extension of the morbid action from adjoining parts, as the rectum, cæcum, colon, or omentum. Uro-cystitis has thus been observed in the course of colonitis or inflammatory dysentery, of peritonitis, and of inflammation of the generative organs in females; and the connexion of these maladies has often been rendered manifest by examinations after death. Inflammation may also attack all the coats of the bladder either primarily or consecutively. The former is of rare occurrence, the latter is much more frequent, owing to its extension from the mucous or serous surface of the organ, and to injuries and operations.

41. Uro-cystitis, with reference to its *seat*, may be viewed, 1st. As to its limitation to the mucous surface of the organ; 2d. As to its extension to the coats forming the parietes; 3d. As to the part of the viscus most frequently affected either primarily or secondarily; 4th. As to the nature of the morbid action; 5th. As to its consequences; and, 6th. As to its complications. Each of these heads will be considered in detail.

ii. INFLAMMATION OF THE MUCOUS SURFACE OF THE BLADDER.—SYNON.—*Blennorrhagia vesicalis*, Swediaur. *Dysuria mucosa*, Cullen. *Catarrhus vesicæ*, Lieutaud. *Rheuma vesicæ*, Stoll. *Pyuria mucosa*, Sauvages. *Catarrhe de la vessie*, Fr. *Muco-cystitis* (Author). [*Cystorrhœa*]

42. Inflammation of the mucous coat of the bladder generally proceeds from the common causes of inflammation, and from those which are usually productive of cystitis (§ 84, *et seq.*), especially the extension of inflammation of the urethra to the neck and internal surface of the organ, the use of irritating injections, of irritating diuretics and aphrodisiacs, the irritation of calculi, &c. This form of cystitis is of frequent oc-

currence, and presents every degree of activity, from the most acute to the most chronic, owing to the diathesis and habit of body, age, and mode of living of the patient, and to its causes.

43. *A.* The acute form of the disease is characterized by severe pain, increased by pressure, sense of heat or tension in the hypogastric region, and uneasiness in the perineum, and by frequent urgent calls to discharge the urine, attended by difficulty and increased pain. These symptoms are often preceded by chills, horripilations, or rigors, and are followed and attended by febrile reaction and its usual concomitants. Sometimes neither chills nor horripilations are felt, especially when the disease has extended from the prostate gland or the urethra, the pain in the region of the bladder, and the frequent desire to urinate being the invading symptoms. The urine is passed often and in small quantities, with much smarting heat and repeated efforts. It is generally acid, of a deep lemon or orange colour; at first clear, but in a day or two numerous small shreds of lymph or mucus are seen floating in it. Sometimes the urine is reddened and turbid, and deposits a thick sediment, consisting chiefly of a muco-puriform matter. In a few days the irritation and febrile disturbance are diminished; the severity of the pain in the region of the bladder is abated; but often, even when this abatement is well marked, the quantity of mucus or of muco-puriform matter in the urine is increased. The local and symptomatic irritation, and the frequency and the difficulty of urinating, generally more or less subside about the same time.

44. *B.* The consequences and terminations of acute muco-cystitis vary with the severity, the causes, and the nature of the attack, and the constitution and other circumstances of the patient. If the inflammation proceed no farther than the mucous surface of the neck of the bladder and of the parts in the immediate vicinity, the above symptoms diminish gradually, and the disease terminates in resolution. But very different consequences occasionally ensue. If the inflammation be very acute, it may rapidly extend to all the tissues of the organ, and even partially to others in the vicinity, the disease becoming extremely dangerous or even fatal. In this case it passes into a state of uro-cystitis, to be noticed hereafter. More frequently, however, the acute inflammatory symptoms gradually subside, especially the febrile action, but the local ailment subsists for some time, or continues with greater obstinacy, the disease becoming chronic.

45. *C.* Chronic inflammation of the mucous surface of the bladder sometimes supervenes on the acute, as just stated; but it often occurs in a primary form.—In this latter case its invasion is slow, and it is not accompanied with any or much febrile disturbance, unless the inflammation assume an intermediate grade between the acute and chronic. Sometimes the febrile action is very slight or remittent, and the local symptoms are chiefly remarkable, especially irritability of the bladder, pains in its region, or at the extremity of the urethra, previous to and at the time of passing the urine. This excretion furnishes, especially as it cools, a mucous or muco-fibrinous deposit, of various shades of colour in different cases, and often an ammoniacal odour. A sense of weight in the perineum, or of heat in the bladder and along the urethra, frequent calls to micturate, and shooting pains to the anus, are also

often experienced. The discharge of mucus in the urine is more or less considerable—hence the term *catarrhus vesicæ*—but varies much in different cases and at different times.

46. *A.* Sometimes the disease is slight; but in old cachectic subjects, and when complicated with disease of the kidneys or of the prostate, or with both, it is often dangerous, or even proves fatal. In this latter state, or when the disease has gone on to ulceration, the heat in the bladder and urethra amounts to scalding, the desire to pass the urine becomes more frequent and urgent, and the efforts more violent or straining. The expulsion of the last portion of urine is more or less painful; and retention of urine is not infrequent, owing to the obstruction caused by clots of mucus or fibrinous exudation lodged in the passage. Pain is felt at the extremity of the penis, in the perineum and anus, sometimes in the loins and thighs. There are thirst, costiveness, or irregularity of the bowels, uneasiness or restlessness, wasting of flesh, and loss of strength.

47. *b.* The mucus discharged in the urine varies much in quantity and appearance. It is sometimes small, at other times or cases it is so great as to amount to pounds in the twenty-four hours. In small quantity the urine is rendered turbid or flaky by it, and it settles to the bottom of the vessel. It is occasionally stringy, ropy, or of a lumpy or viscid consistence. The urine is generally acid early in the disease, but it becomes neutral or alkaline as the mucous secretion is increased. When acute muco-cystitis passes into the chronic the quantity of mucus is often considerable, in some cases extremely great, forming glairy or ropy streaks in the urine, which are afterward deposited. When the disease has not been of long duration, the mucus in the urine is generally whitish-gray or yellowish-gray, tenacious or stringy, inodorous, and presenting no distinct appearance of pus. But in the more chronic or obstinate cases a purulent matter is evidently present, mixed with and often more or less predominating over the mucus. In these cases the morbid matter is less abundant, less tenacious, of a yellowish colour, more readily miscible with the urine, and is sometimes streaked with thin bloody filaments. It is also sometimes fetid, is not so readily deposited at the bottom of the vessel as the mucous secretion, nor is it so tenacious. It does not form albuminous flocculi when boiling water is poured upon it, nor does it coagulate, or but imperfectly, when boiled. When these appearances are seen in cases of considerable duration, ulceration of the mucous surface, affecting chiefly the follicles, and the extension of inflammation to the connecting cellular tissue, may be inferred. This inference will be still more fully borne out if there be slight fever assuming a remittent, or intermittent, or hectic form, constant pain in the organ, emaciation, restlessness at night, and the undoubted presence of pus in the urine, with more or less alkaliescence.

48. *c.* Pus may be distinguished from mucus not only by the above appearances, but by its being miscible with the urine, which it renders opaque. If the urine contain pus as well as mucus, the former is deposited upon the latter, and is yellower in tint, and opaque, the mucus being translucent. The microscope aids the diagnosis in these cases by showing the presence of pus-globules of the diameter of 1-2500th part of an

inch. If the urine be acid, the nucleus of the pus-globule may be seen without the aid of reagents; but, as it is more frequently alkaline, the addition of a drop of acetic acid will bring the nucleus into view by rendering the corpuscle more transparent. \* A copious sediment resembling pus is sometimes produced by a large quantity of triple phosphate in the urine. But the nature of this is shown by its solution in nitric acid, and by the shape of the crystals under the microscope. When the urine containing pus presents an acid reaction, pyelitis may generally be inferred; when it is alkaline, cystitis may be considered to exist. Purulent urine becomes clear on standing, a more or less abundant sediment is formed, the supernatant fluid is often of a greenish-yellow tint, and contains albumen.

49. Dr. PROUT states that, in the advanced stage of the disease, the mucus in the urine is diminished, it becomes opalescent and of a greenish tint, and can in part be easily diffused through the urine, rendering it glairy or opaque, or milky like pus, the morbid matter being in fact mucopuriform. The urine is now generally deep-coloured, or serous, or alkaline, having an ammoniacal odour, and effervescing with an acid. In this latter case there is an excess of carbonate of potash or of soda in the urine, derived from the serum of the blood. "When these symptoms have continued for a longer or shorter period, the urine becomes scanty, still more high coloured, and occasionally even acid; the mucus, and even the pus, gradually diminish, and almost disappear; and after a short period of comparative ease the patient expires."

50. *d. Intermediate grades of muco-cystitis*, between the acute and chronic states of the disease, are occasionally met with in practice. These have often been termed *sub-acute*. They are to be distinguished by more or less of the symptoms already adduced, generally all of them, but in different degrees of severity, and attended by remittent or hectic febrile action. They may occur primarily or follow the acute, which may subside into the sub-acute, and ultimately into the chronic state, terminating at last in ulceration and thickening of the organ or some other structural lesion. The chronic form of the disease may even pass into the acute, although not so often as the converse, either having presented an intermediate grade of morbid action, or having, owing to some exciting cause, suddenly assumed the acute form. In this latter case the extension of inflammation still farther should be dreaded and guarded against.

51. *e. The duration of muco-cystitis is extremely various*: it may be from one month—it being seldom much less in the acute—to two or three months in the sub-acute, to several months to two or three years in the chronic. It depends entirely on the cause, the age, and constitution of the patient, on the degree to which the inflammation may have extended to the other coats of the viscus and to adjoining parts, and on the complications the disease may have presented. The same circumstances also influence the prognosis and treatment (§ 83, 89).

iii. INFLAMMATION OF ALL THE COATS OF THE BLADDER.—*Cystite profonde*, CLOQUET; *Cystitis vera*—*true Cystitis*.

52. This form of cystitis is not often met with as a primary disease. It much more frequently supervenes on one or other of the forms of muco-

cystitis, and it occasionally occurs from the extension of inflammation from contiguous viscera; as from inflammation of the uterus and ovaria or Fallopian tubes, or of the rectum, colon, cæcum, peritonæum, omentum, &c.; from extensive hæmorrhoids, and from diseases of the prostate. It will be seen that true cystitis, in some of these consecutive states of occurrence, commences in the peritoneal surface of the fundus, and that it extends to all the coats. It is, indeed, extremely rare for true cystitis to commence in this part of the structure of the bladder, unless when it supervenes in the manner now alluded to.

53. *True Cystitis* is thus more frequently secondary or consecutive, and but rarely primary. But whether originating in the one way or in the other, it is a severe and dangerous disease; and, owing to its consequences, is often speedily followed by the most serious effects. While the mucous coat only is the seat of inflammation, the function of the muscular coat is seldom affected in such a manner as to allow inordinate accumulations of urine within the viscus, unless the disease is attended by an obstruction to the discharge of the urine by associated disease of the prostate or urethra, or by the impaction of a calculus or fibrinous clot in the neck of the bladder. When, however, these obstructions occur, the inflammation of the mucous coat soon extends to the other coats; the previous irritability of the muscular coat is overcome by the distention consequent on obstruction, and rapidly passes into almost total paralysis or incapability of contraction, one of the most dangerous states of the organ in cystitis.

54. When true cystitis follows muco-cystitis or catarrhus vesicæ, the abundant mucous or muco-purulent secretion which characterized the latter is either much diminished or ceases altogether. This arises from the transfer of the inflammatory action chiefly to the more external coats of the bladder, and the diminution of it in the surface, which was formerly its only seat. The occurrence of this change has led Dr. PROUT to think that the inflammation of all the coats of the viscus is of a different kind from that of the mucous coat; but I infer that the difference consists merely in the different functions of the parts affected in both these forms of cystitis.

55. *True Cystitis* presents various grades of activity, from the most acute to the chronic. The pathological states through which the disease passes, and the consequences to which they lead, are also diverse, and not always referable to the violence of the attack, but are dependent upon a number of circumstances connected with the causes, complication, and other peculiarities of the case. Thickening of the coats of the bladder, owing to an infiltration of an albuminous serum into the connecting cellular tissue, is very frequent, especially when the inflammation is sub-acute or chronic, or has extended from the mucous coat and is dependent upon obstruction to the discharge of urine or the presence of calculi. In these cases the distention of the bladder is a frequent occurrence; and even when this form of the disease is primary, and is not accompanied with obstruction to the discharge of urine, a loss of the power of the muscular coat, and consequent retention of urine, is a frequent attendant upon it. Although true cystitis affects all the coats of the bladder, a part of the organ may be more particularly affected by it than the

rest, especially the parts near the neck, and extending thence to the ureters. This is especially the case when the disease has followed inflammation or other morbid states of the prostate gland, urethra, rectum; or has proceeded from hæmorrhoids, or from injuries caused by the use of the catheter, by lithotomy, lithotritry, or other operations.

56. *A. Acute Cystitis.*—*a.* The symptoms of this state of the disease are, generally after chills or rigors, severe pain, at first behind, afterward above the pubes, a sense of uneasiness in the perineum, heat and tenesmus, and heat and smarting in the course of the urethra. The patient has frequent calls to pass urine, which are always attended by more or less difficulty, often amounting to dysuria. The urine at last escapes only by drops, with more or less scalding and pain, and ultimately with unavailing efforts to discharge it. When the symptoms arrive at this pitch much anxiety and tension of the abdomen are experienced. The distended bladder rises above the pubes, and the hypogastric region is very tender. The frequent calls to pass the urine and the dysuria may mislead the physician, a large quantity of water accumulating and causing injurious distention of the bladder before the circumstance is suspected. This accumulation may be explained by the irritable state of the sphincter vesicæ, the tumefaction of the inflamed parts having diminished the outlet of the bladder, and by the want of due action in the muscular coat, owing to the inflammation in which it and the other coats are involved. Hence it is thrown into frequent and inefficient action, a portion of urine is often passed; but as soon as it reaches the irritable and inflamed parts immediately below the sphincter, spasm of these parts, and of the sphincter itself, takes place, which the contractions of the fundus are unable to overcome. The secretion of urine proceeding, distention so great as to destroy the powers of reaction results, and complete paralysis of the muscular coat supervenes. If in this state a portion of the urine passes off, it is owing to partial relaxation of the sphincter for a moment, and to the position admitting of the discharge by gravitation. This difficulty of voiding the urine and the consequent accumulation are not owing to the muscular coat of the bladder only; for in many cases the parts near the neck of the bladder are chiefly affected, the tumefaction of these being so great as nearly to obliterate the canal, and mechanically to obstruct the flow of urine and the introduction of the catheter. In complications of the disease, with enlarged or inflamed prostate, this is obviously the case, a circumstance tending materially to influence the prognosis. Independently of this complication, there is every reason to infer, from the nature of the morbid secretion and structure of the parts, that this swelling contributes its share with the other lesions to the production of this very unfavourable symptom. In cases of cystitis produced by injuries of the spine, the paralytic state of the muscular parts of the bladder is the cause of the accumulation of urine and of the consecutive inflammation; but in other cases the inflammation is the cause of the retention and of the loss of muscular power, as above stated.

57. When the disease has reached this stage, and the accumulation in the bladder is manifest, the symptoms soon run on to a dangerous height, if relief be not soon afforded by medical or surgi-

cal treatment. The patient is anxious, distressed, and fevered, the pulse is frequent and hard, the tongue white and loaded, the appetite is lost, thirst is great, costiveness with frequent calls to stool, painful tenesmus, and difficulty of passing a motion, especially when the disease is seated chiefly about the neck of the bladder, or is complicated with disease of the bladder, as frequently is the case, especially in old men, are also experienced. In these cases, and in others proceeding from some irritation acting in a special manner on the bladder, as when the cystitis has arisen from the improper use of cantharides, the presence of calculi, &c., the urine which is passed is often sanguineous, or contains a considerable quantity of blood.

58. The disease, having reached the state now described, will often evince signs of diminution, or rapidly present those of a still more dangerous character. If accumulation of urine and over-distention of the bladder have been prevented, and the treatment otherwise judicious, the former will generally be the result. But when the bladder still continues over-distended, great prostration of strength, with extreme restlessness, takes place; the pulse becomes small, frequent, intermittent, constricted, and at last weak and scarcely perceptible; the skin is hot and dry, afterward moistened with a urinous or fetid perspiration; the tongue is dry, the thirst extreme; and to these sometimes supervene cardiacalgia, vomiting, hiccough, stupor or low delirium, cold extremities, sometimes convulsions, coma, and death.

59. *b.* Cases of true cystitis occasionally occur wherein little or no urine accumulates in the bladder, owing to the inflammation and consequent tumefaction of that part of the viscus surrounding or in the vicinity of the opening of the ureters into it, or to the effusion of coagulable lymph having entirely shut up their outlets. In these cases inordinate distention of the ducts and pelvis of the kidneys must occur, and, in addition to the above symptoms, those of dangerous disease of the kidneys and suppression of urine supervene, especially fulness, pain, and tenderness in the loins, numbness of the limbs, vomiting, constant hiccough, cold or urinous perspirations, rigors, subsultus tendinum, coma, &c.

60. *c.* When cystitis has followed the healing of old eruptions or ulcers, or the sudden stoppage of accustomed discharges, as the hæmorrhoids, the catamenia, or fluor albus, or if it have arisen from the misplacement or metastasis of rheumatism or gout, or if it have attacked persons of these diatheses, the several tissues of the bladder are liable to be affected nearly at the same time; but the symptoms are generally less severe than in the strictly primary and phlogistic form of the disease, and more frequently assume a sub-acute form, or some grade intermediate between this and the chronic form next to be described.

61. *d.* The duration of the disease in persons of the phlogistic diathesis, and at an early age, often is extremely short. True cystitis may reach its height as early as the third or fourth day, and its termination in the course of the first or second week. But in more delicate or less inflammatory constitutions, or in those weakened by previous disease, if it assume the acute form, it is more inclined to lapse into a sub-acute or chronic state, and to continue an indefinite time. It may, moreover, assume from the commencement a sub-acute or intermediate character between the acute

and chronic. But in all cases of this form of cystitis very much depends upon the nature of the exciting and concurring causes, the complications which certain cases present, and the attention paid to the unloading the bladder of its contents, and to other indications and means of cure.

62. *c. Terminations of Acute Cystitis.*—True cystitis terminates—1st. In resolution, with a gradual amelioration of all the symptoms; 2d. In the chronic state, with relief of the most urgent symptoms, and continuance of a dull pain, uneasiness, and tenderness in the region of the bladder, dysuria, &c. (§ 65, *et seq.*); 3d. In suppuration, when the disease is very acute, this issue generally occurring within twenty-four hours after the disease has reached its acme; 4th, and very rarely, in gangrene; 5th, and still more rarely, in rupture of the viscus.

63. (*a*) *Suppuration* is preceded and attended by pain and throbbing in the region of the bladder, or behind and above the pubes, and occasionally referred to the seat of the rectum, by horripilations, chills, or rigors, followed by flushes of heat, and sometimes by perspiration. There are often also painful tenesmus, costiveness, and fever. The urine afterward has a turbid, purulent appearance, or contains a whitish-yellow matter, sometimes streaked with blood, and has the odour characteristic of pus. In many of these cases the purulent secretion proceeds from the internal surface of the bladder, but small abscesses formed in the parietes of the viscus have opened internally and furnished this secretion. This latter is more frequently the case when the parts near the neck of the organ are more especially affected. CHOPART has recorded several instances of this occurrence, as well as of another, more unfavourable, when the abscess is formed more exteriorly, and makes its way, externally to the bladder, into the loose adipose cellular tissue at the bottom of the pelvis. If in such cases the patient survives, the abscess ultimately points in the perineum, or near the margin of the anus. Abscess of the bladder is seldom so situated as to break into the peritoneal cavity. In all cases of abscess of this viscus the danger is great, particularly in the latter cases.

64. (*b*) *Gangrene* may supervene in the most acute cases, or in cachectic constitutions; but it is a very rare occurrence, and is never met with unless the disease be attended by retention of urine of two or three days' duration. In these circumstances an eschar or small sphacelated spot is formed at one or more situations in the organ. This advances, and at last the bladder bursts, and the urine is effused, generally into the abdominal cavity. M. CLOQUET thinks that the rupture may occur without the previous sphacelation, from the distention, the greater tenuity of the bladder, and the deficient support of its parietes at this situation. Admitting that ruptures of the bladder are generally in the fundus, yet they are less to be imputed to want of support in this situation, and to greater tenuity, than to previous ulceration and deficiency of vital cohesion characterizing the advanced stages of acute inflammation, although these circumstances may contribute to the event. But very few of the cases of rupture that occur depend upon previous sphacelation, which is an extremely rare occurrence in this disease.

65. *B. Chronic Cystitis.*—When the acute form of true cystitis has not terminated completely in

resolution, it frequently passes into a chronic state of the disease. But this form may exist from the commencement, and, appearing in a mild state, it is often neglected, and hence becomes an enduring disease. As in other inflammations, cystitis is observed of every intermediate grade of severity and of duration, from the most acute to the most chronic, according to the nature of the exciting and concurring causes and the peculiarities of the individual. The consequences resulting from the sub-acute or chronic forms of cystitis also vary with the severity of the attack. When the chronic is merely a continuation of the acute in a less severe degree, the nature of the disease is manifested by the persistence of the local symptoms especially, which are of a nature readily to be recognised and understood, and are chiefly those already adduced, but in a milder form.

66. When chronic cystitis occurs primarily, its accession is sometimes slow, and scarcely so severe at first as to excite the anxiety of the patient. In other cases it is of a much more marked character, and more nearly approaches a sub-acute or an acute form. But in general it is characterized by permanent pain referred to some part of the viscus, by frequent calls to void the urine, attended by difficulty, as if occasioned by stricture of the urethra; by the presence of mucus or purulent matter in the urine; by tenesmus at stool and costiveness; by slight fever, especially in the evening, and sometimes by fever of a remittent or intermittent form; by a loaded tongue; by inability to retain much urine at a time; and by an exacerbation of some or of all the symptoms after fatigue, exposure to cold, or errors of regimen, especially after drinking spirituous, vinous, or malt liquors. These symptoms vary in degree, and one, more, or even all of them, are more severe the more nearly the disease approaches a sub-acute or acute form.

67. The duration of this form of cystitis varies, according to the severity of the symptoms, from two or three months to as many years, or even longer. An acute or sub-acute state may supervene upon the chronic and shorten its duration, or the same result may follow the extension of disease to adjoining parts and the presence of serious complications. When it arises from calculi in the bladder, or from disease of the prostate or urethra, thickening of the walls of the viscus is a common consequence. It may, when it approaches the acute or sub-acute forms, terminate in abscess, in ulcerations, or perforation, or give rise to other lesions by extension of the inflammation to adjoining parts, as noticed in respect of the acute disease (§ 63).

68. *C. Ulceration of the urinary bladder* may result from any one of the forms of inflammation of the mucous coat of the organ already noticed, but most frequently from the sub-acute, chronic, and most protracted states. It may, however, also follow the acute form and the more chronic states of true cystitis. It is often difficult to decide as to the existence of ulceration; but when disease of the bladder has been of long duration, the pain severe and continued, with a frequently recurring desire to micturate, and an increasing difficulty and pain in passing the urine, then the existence of this lesion should be suspected, and, if the urine presents the appearances stated above (§ 48), especially if it contains pus streaked with blood, it need not be doubted. *Ulceration of the*

bladder may take place differently : it may commence in the mucous follicles, especially in the more chronic cases ; or it may follow the acute form, lymph being first exuded from the inflamed surface, and subsequently detached, leaving this surface tender and susceptible of irritation from the urine, and liable to experience ulceration from the continuance of the irritating cause. In acute cases the mucous surface may thus be nearly all destroyed by the softening and ulcerating processes produced and perpetuated by the urine on the inflamed surface, the walls of the viscus becoming thickened, even although the muscular coat may be laid bare in parts.

69. When the ulceration is seated or commences in the follicles, *perforation* of the bladder may result, the disease having assumed most frequently a chronic form. When ulceration or destruction of the mucous coat follows acute cystitis, all the coats forming the parietes of the organ rapidly become implicated, and the disease soon terminates fatally. The more limited states of ulceration, especially when commencing in the follicles, may perforate the coats of the viscus, and, having reached the peritoneal surface, occasion the exudation of lymph, by which the bladder becomes united to adjoining parts, thereby preventing the escape of urine, or forming a fistulous opening into some other viscus. In this manner a fistulous communication may be formed between the fundus of the bladder, the sigmoid flexure of the colon, or the œcum, or the ileum, &c. When a fistulous opening is thus formed between the bladder and any portion of the bowels, feces may pass into the bladder, unless the opening be formed between the under surface of the bladder and the rectum, and then the urine is usually voided with the feces. Fistulous communications between the bladder and the rectum are more frequent, especially in females, than between the former and other portions of the intestinal canal. When communications are formed in this situation, either by ulceration commencing in the bladder or in the rectum, an abscess below the reflected portion of the peritoneum often forms, owing to the inflammation of the connecting cellular tissue caused by the urine or by the feces. Mr. Coulson (*op. cit.*, p. 140) has recorded some interesting cases of fistulous openings between the bladder and intestines, to which I may refer the reader. Ulceration and perforation are always attended by hypertrophy or thickening of the coats of the bladder, whether they be consequent upon muco-cystitis or the more chronic or sub-acute states of true cystitis. When the ulcer is seated in the posterior and inferior part of the bladder, it may penetrate the coats so that the urine will pass into the cellular tissue between the bladder and rectum, producing the most destructive effects.

70. iv. COMPLICATIONS OF CYSTITIS.—One or other of the forms of cystitis may be associated with some other disease or structural lesion. These diseases may be the causes of the inflammation of the mucous coat of the bladder, as well as its complication. This is especially the case with gonorrhœa, gleet, stricture of the urethra, syphilis, calculus in the bladder, rheumatism, gout, &c. *Gonorrhœa* often induces a severe and obstinate form of muco-cystitis, the discharge from the urethra being diminished as that from the bladder becomes more copious and the other symptoms more distressing. On the other hand, the chron-

ic forms of muco-cystitis, especially when they go on to ulceration, perforation, &c., induce disease of the kidneys, most frequently of the left kidney (RAYER, RICHTER, P. FRANK, COULSON, &c.). In these latter cases a dull pain is felt in the loins, is increased by pressure, and is ushered in by chills, rigors, sickness at stomach, and an albuminous urine, which also contains large quantities of puriform matter, often tinged with blood.

71. With ulceration of the mucous coat, hypertrophy of the muscular coat, contraction and thickening of the parietes of the organ generally result. The bladder, owing to its irritability, is constantly contracting upon the urine poured into it ; and spasm of the sphincter often causes a regurgitation into, or an obstruction of the ureters ; which thus become distended and tortuous, and still farther changes are thereby induced. " The mucous membrane, extending upward along the ureters to the pelvis and the infundibula of the kidneys, becomes inflamed and rough, and pours out a quantity of pus. The glandular structure of the kidney undergoes from pressure slow absorption. The capsule adheres with preternatural firmness to the exterior of the gland. Upon making a section of a kidney so diseased, we find that, although apparently of large size, it consists in great part of dilated tubes, and that the true vascular or secreting part is in smaller proportion than usual."—(*Op. cit.*, p. 144.)

72. The complications either of muco-cystitis or true cystitis are chiefly with diseases of adjoining parts, and arise from the extension of inflammatory action, either to these parts from the bladder, or from the latter to the former. Inflammation of the urethra, prostate gland, strictures of the urethra, calculus vesicæ, hæmorrhoids, colonitis or inflammatory dysentery, inflammations of the rectum and of the uterine organs, and kidneys, &c., may severally extend to, or excite inflammation of the bladder. On the other hand, this latter may involve the adjoining parts : it may extend from the fundus to the omentum, or to some of the convolutions of the intestines, or it may occasion peritonitis. This is not a frequent occurrence ; but firm adhesions of one or other of these parts to the fundus of the bladder have been found on rare occasions, where, from the history of the cases, the bladder was the original seat of disease.

73. Inflammation may extend from the mucous coat of the bladder to the ureters, and along their course even to the kidneys ; but this very frequent and important complication of uro-cystitis is most probably not often produced in this manner, but much more frequently by the occlusion of the ureters where they pass through the coats of the bladder, owing to the tumefied state of the inflamed parts at this situation. In this case the urine is secreted for a while, but cannot pass into the bladder, owing to this condition of parts. Inordinate distention of the ureters, pelvis, and tubular structures is the consequence, and serious disease and disorganization, not only of these parts, but also of the constitution, result.

74. The extension of inflammation of the bladder to the uterine organs is not infrequent ; occasioning not merely adhesions between the serous surfaces, but also, particularly when cystitis is consequent upon, or is attended by retention of urine, retroversion or obliquities of the uterus, leucorrhœa, &c. The most frequent complication

of cystitis is stone in the bladder, the inflammation being consequent upon, and generally occasioned by the solid concretion. The frequent connexion also of the several forms of uro-cystitis with gout and rheumatism, either as consequences of the misplacement or metastasis of these, or as occurring from other causes, owing to the predisposition to urinary disease occasioned by them, should not be overlooked when ascertaining the causes and the relations of cystitis, or when determining the indications and means of cure.

75. v. APPEARANCES AFTER DEATH. — These vary much in different cases, and are more generally the consequences than the states forming the early, or even the advanced, states of the disease. — *A. After acute muco-cystitis*, the inner surface of the bladder is thick, rough, of a reddish-pink hue, from capillary distention, with small ecchymoses, owing to exudation from the congested capillaries. The inflammation in most fatal cases is found to extend over the whole inner surface, although greatest in some parts, especially near the neck of the organ. Coagulable lymph is sometimes found covering or attached to the mucous coat. This tunic, in the most acute cases, may be detached from the muscular in parts, or even throughout, forming a grayish layer resembling a false membrane. In many instances the mucous coat has been destroyed by ulceration; "sometimes, however, round ulcerated spots, the size of a sixpence, are found in different parts, with elevated edges and a red surface." Ulceration generally commences at or near to the neck of the bladder, and extends more or less to the fundus; but it sometimes begins in the latter, and advances to the former. In the most severe cases the muscular coat is involved in the inflammation, presenting gangrenous or disorganized spots. One or other of the kidneys is also generally diseased, the pelvis being dilated or ulcerated, containing pus, and the ureters also being dilated and ulcerated at their vesical extremities.

76. *B. In the slighter or early states of chronic muco-cystitis* the mucous coat is found, in cases of death from other diseases consequent on the former, injected, discoloured, thickened, and softened, and its follicles enlarged and inflamed. It separates readily from the adjacent coat, is abraded in parts, and is even detached in spots by extravasations underneath. The parietes of the viscus are thickened and contracted, the muscular coat is greatly hypertrophied, and ulceration of the mucous coat penetrates to the muscular, or even farther (§ 68, 69). When the ulceration is extensive, the hypertrophied muscular fibres appear, and resemble the columnæ carneæ of the heart, presenting a purplish-red colour; the mucous coat between the columns thus formed being pale, soft, and swollen. Pouches, or sacs, generally coexist, with dilated ureters, between these muscular columns, and are formed by the contractions of the bladder and of the abdominal muscles, in expelling the urine, forcing the mucous coat in places between the muscular fibres. These pouches are lined with a diseased mucous coat, which secretes an alkaline mucus, and are "sometimes the receptacles of a mortar-like matter, and finally of calculi, consisting generally of phosphate of lime." As the disease proceeds in the mucous coat it extends to the ureters, to the pelvis, and to the tubular structure of the kidneys;

and pyelitis supervenes. Ultimately the ureter leading to the kidney affected becomes dilated, tortuous, its lining membrane inflamed, granulated, or ulcerated, or sometimes covered with lymph. The pelvis and infundibula are much dilated, while the secreting structure of the kidney is reduced to a thin layer.

77. *C. In the more chronic states* and other cases of *muco-cystitis*, patches of a red colour, more or less deep, or from a bright red to a violet shade, are found in the mucous coat; and small ulcerated specks or points, apparently affecting the mucous follicles, are seen in these patches. In the more chronic cases the ulcers are of considerable size. When numerous they are generally small. Sometimes an albumino-puriform matter, adhering at points of the mucous surface, gives it an ulcerated aspect on a superficial view; and occasionally this surface appears elevated at numerous points, owing to an albuminous exudation in the subjacent cellular tissue. The whole internal surface is but rarely affected, although the greater part generally is, in the form of large irregular patches. In protracted cases the mucous surface is thickened, and this change often extends to the connecting cellular tissue; while the blood-vessels are more numerous and more engorged than natural. With these appearances the bladder is generally contracted, and the mucous coat forms a number of large wrinkles or folds, is often softened, and is occasionally incrustated, or covered in parts with a calcareous deposit. The prostatic gland is often enlarged in these cases, is somewhat diminished in consistence, and readily admits of being divided.

78. *D. In true cystitis*, especially when chronic, in addition to increased vascularity, more marked in some places than in others, the parietes of the bladder are much thickened, and more or less contracted; but the extent of these changes varies greatly, being generally greatest in cases of chronic cystitis arising from the presence of stone. In some cases the thickening is moderate, yet attended by a varicose state of some of the veins of the viscus. Adhesions to adjoining parts of the fundus of the bladder, ulcerations, &c., are also seen in the circumstances and complications of the disease described above (§ 63-69).

79. vi. DIAGNOSIS. — *A. Muco-cystitis*, when acute, may be mistaken for inflammation of all the coats of the bladder; but in the latter the desire to void the urine is much less frequent than in the former, and sometimes is not experienced until a large accumulation has taken place, and then it occurs in most severe paroxysms. The sense of scalding along the urethra felt in muco-cystitis is either slight, or absent when all the coats are inflamed. Occasionally the power to pass the urine is lost in this latter form of the disease, even when the desire is most urgent, and the act can be accomplished only after repeated efforts, or by surgical aid.

80. Many of the symptoms of acute muco-cystitis are experienced when stone is present in the bladder. But in cases of stone the pain is chiefly felt after the bladder has been emptied; whereas in acute muco-cystitis the pain is most intense when the bladder contains urine, and it subsides when the viscus is empty: in cases of stone, also, larger quantities of blood are passed than in muco-cystitis, and the urethra is seldom so irritable. (Coulson.)

81. *B. Irritability of the bladder* is to be dis-

tinguished from muco-cystitis and true cystitis by the symptoms noticed above (§ 11), and by the severity of the local affection, and of the constitutional disturbance. When, however, the irritability depends upon organic disease of the kidney, the diagnosis is more difficult. Mr. Coulson remarks that the intense pain which attends inflammation and ulceration of the mucous coat of the bladder soon exhausts the patient, while in irritable bladder from diseased kidney there is sometimes, but not always, pain in voiding the urine; that the frequency of micturition is the most distressing symptom; and that, even when pain exists, it is never so severe as to wear the patient out, but may be, and often is, endured for years.

82. *C. The chronic states of muco-cystitis* are readily recognised. When mucus is passed in the urine in small or moderate quantity it may be mistaken for the involuntary discharge of semen, or of the prostatic fluid, which accompanies the evacuation of the fæces or of the urine in some persons; but semen differs from mucus in its color, in its property of liquefying on cooling, in its insolubility in water when recent and thick, and its solubility when liquid, and in the radiating crystals which it produces after evaporation. The prostatic fluid may be distinguished by its remarkable transparency, by its stringy and slimy properties, and by its retention of these conditions until it is dried. The prostatic secretion is often mistaken for the seminal in cases where it is discharged, both being passed immediately after the bowels and the bladder are evacuated; but the prostatic fluid is passed much more frequently than the seminal, which is thus voided much more rarely than is often believed to be the case. Chylous urine is different from the urine voided in muco-cystitis, in being of a uniformly whitish hue, and the sediment formed by standing readily mixes with the urine on shaking; whereas the urine in this form of cystitis is at first turbid, and on standing the sediment becomes viscid, ropy, flocculent, or muco-puriform, or even purulent, and it has the appearances already noticed (§ 47-49).

83. *vii. THE PROGNOSIS* depends much upon the age, constitution, diathesis, and habits of the patient, and on the exact seat, severity, and duration of the disease. It may even still more depend upon the consecutive lesions already produced, and upon the presence or absence of complications. If the disease be primary and uncomplicated, and the patient young or middle-aged, and of a sound constitution, or has not previously been subject to disease of the urinary organs, the prognosis is *favourable*; but, on the contrary, if he be aged, cachectic, has been subject to previous disease of the urinary organs, to stricture, or to any of the complications mentioned above (§ 70, *et seq.*), especially to disease of the kidneys, and still more particularly to this latter, occurring consecutively upon chronic muco-cystitis, the prognosis is *unfavourable*. In the more acute cases, as well as in the subacute and chronic, if the pain continue, notwithstanding a judicious practice; if the micturition be still frequent; if the urine be loaded with a muco-puriform matter, epithelium, and a little blood; if a dull, heavy, and continued pain be felt extending from above the pubes to the sacrum or sacro-iliac symphyses, and especially if it be experienced in the loins and extend to the thighs; if emaciation and hectic

be marked; and if vital exhaustion be rapid or extreme—ulceration of the bladder, and consequent disorganization of the kidney, may be inferred, and a fatal issue be expected. If the states of true cystitis be followed by retention of urine, or if either form be followed by suppression, renal symptoms supervening, and no urine being found in the bladder, the danger is generally extreme. Whenever any of the severe symptoms mentioned above (§ 56, *et seq.*) occur, whatever may be the stage, form, or progress of the disease, a most cautious prognosis should be formed.

84. *viii. CAUSES OF CYSTITIS.*—*A.* The several forms of cystitis are most frequently met with in persons advanced in age, and in adults—particularly in the former. MM. LESAIVE and BOISSEAU have, however, seen them in children between two or three years of age, and I have met with them as early as four and five years; but instances at this age are very rare, unless when accompanied with calculus in the bladder, or after injuries and operations. Cystitis frequently occurs in cold and humid climates, especially that form of it which is limited to the mucous coat; and it is common in persons addicted to fermented or spirituous liquors. Sedentary habits and occupations also *predispose* to it, especially in aged persons who are either confined to a sitting posture or to bed. An habitual neglect of immediately attending to the first desire of voiding the urine is a usual predisposing as well as exciting cause; the retention of this excretion occasioning irritation of the mucous surface and over-distention and diminution of contractility of the muscular coat. Females are less subject than males to muco-cystitis; but they appear quite as liable to the acute form of true cystitis, while they are less frequently affected with its chronic state, and to the complication of the disease with calculus and with disease of the kidneys. This partial immunity is owing to calculous concretions being less frequent and more easily removed in females; while diseases of the prostate and of the urethra are very frequent causes of the forms of cystitis in the male sex.

85. There are, perhaps, few causes which more frequently predispose to inflammations of the bladder than long-neglected disorder of the digestive organs, and especially to those states of cystitis which are complicated with calculous formations. There also seems to be a predisposition constitutionally inherent in some persons to diseases of the urinary organs, and consequently of the bladder, and especially in those of a gouty diathesis. Indeed, both the gouty and calculous diatheses often originate in the same sources, namely, in deficient vital energy, and long-continued disorder of the digestive functions connected with an excessive use of animal food relatively to the amount of exercise in the open air. The connexion of the former state of the system with disease of the bladder is very evident, and the intimate relation which both diatheses hold to each other in respect both of their common sources and of their exciting causes, are satisfactory proofs of predisposition independently of the evidence furnished by experience of the frequency of cystitis in gouty habits. Persons of a serofulous diathesis, or who have been addicted to venereal excesses or to the habitual use of highly seasoned dishes, to much animal food, and to sedentary occupations, are generally disposed to cystitis.

86. *B.* The most frequent *exciting causes* are, too long retention of the urine, exposure to cold and moisture, sitting on damp couches, sofas, or seats, or on cold stones, or on the ground; damp clothes on the lower extremities; damp feet; cold drinks while the body is perspiring; the abuse of diuretic and lithotriptic medicines; the excessive use of common gin; the incautious exhibition of emmenagogues; the internal use of cantharides or turpentine in too large or too frequent doses; the abuse of aphrodisiacs; the introduction of a catheter or sound, especially by unskilled hands; irritating or improper injections thrown into the bladder; the irritation caused by calculi or by morbid states of the urine; external injuries, or blows on the hypogastrium, especially when the bladder is full; coitus when the viscus is distended with urine; horseback exercise, with inattention to the evacuation of the urine; the pressure of the fœtus upon the unemptied bladder during labours; protracted labours and the use of instruments to facilitate the process; operations performed on the bladder; the suppression of accustomed discharges, as of fluor albus, hæmorrhoids, catamenia, and the sudor pedom, to which some persons are subject; the incautious suppression, without suitable internal treatment, of cutaneous eruptions, or healing of external sores or ulcers; the retropulsion or misplacement of gout and rheumatism; inflammations of adjoining parts; obstructions to the discharge of urine from strictures of the urethra, or from enlargement or abscess of the prostate gland; repelled gonorrhœa, and the use of injections for its cure.

87. AMBROSE PARÉ, CABROL, and CHOPART have recorded some cases in which large quantities of cantharides had been taken as a cure for agues, and had occasioned cystitis of uncommon severity and fatal issue. The same result has followed the use of this substance as an aphrodisiac. Cystitis may also be the extension of inflammation from the pelvis of the kidneys to the bladder, or it may arise from the irritation of a calculus in that part of the ureter which passes between the coats of the bladder. It may also supervene in the progress of fevers, particularly of those characterized by stupor, coma, or delirium, or by congestion of the spinal cord, owing to the accumulation of urine of a highly irritating property; the local affection failing to excite the sensibility of the patient in these states, or the attention of the physician. The frequency and importance of this complication in fevers and in diseases of the brain and spinal cord should attract attention to it on every occasion, and on every visit.

88. Injuries and diseases of the spinal cord, its membranes, &c.; compression of, or hæmorrhage on, the cord; concussions of the brain or spinal cord, &c., are frequent causes of retention of urine, and thereby of cystitis. Even sudden jerks, as missing steps on descending stairs, coming with a jerk upon the feet when the body is erect, falling from a height on the feet, especially when much water is in the bladder and a predisposition to inflammation of it exists, are occasionally causes of the disease. It may be remarked, that a single cause will in some persons more certainly produce its effects than the concurrent operation of several causes where little or no predisposition to the disease exists.

89. ix. TREATMENT.—*A. Of Acute Muco-Cystitis.*—The antiphlogistic regimen and treatment

are required in all their details in this form of the disease. General and local *bleeding* should be prescribed, and even repeated, according to the age, habit of body, and constitution of the patient. Cupping over the sacrum, or leeches applied above the pubes or on the perineum, and repeated when circumstances indicate the propriety of the measure, are requisite; and in the milder cases, and in the less robust subjects, the local may supersede general bleeding. In some cases, especially when the symptoms indicate congestion or torpor of the abdominal viscera, or accumulation of sordes in the *prima via*, an *emetic* will be given with benefit. After its operation has been freely promoted the bowels should be sufficiently moved by means of *cooling aperients*, as the infusion of senna with magnesia, the neutral salts, or the carbonate of magnesia and sulphur, &c. Bleeding ought not to be carried too far, especially in the inhabitants of large towns, and in the aged, cachectic, or delicate. Nor should those purgatives which are liable to irritate the rectum or colon be employed; but the bowels ought to be kept regularly open. A warm general *bath*, or hip-bath, is always of service, and should be resorted to as early in the disease as possible after the above means have been employed, and should be repeated as often as the state of the patient will indicate. When the bowels have been evacuated, *opiates*, and *demulcents* or *emollients* are required, both to support the patient and to allay the local irritation. These may be variously combined and exhibited, and may be conjoined with the alkaline carbonates. Morphia, or the preparations of opium, may be used, according to the medicines intended to be given along with either of them or at the same time. I have generally preferred the soap and opium pill, conjoined with an equal quantity of Castile soap. If these fail or lose their effect, emollient enemata should be administered, with either the sirup of poppies or compound tincture of camphor added to them. When these also prove insufficient to allay the local irritation, opiate suppositories may be resorted to, and a belladonna plaster be applied above the pubes, or over the perineum, or a suppository containing some extract of belladonna may be tried. The state of the urine must be daily tested, and, as long as it continues acid, the carbonates of the fixed alkalies may be given, in demulcent vehicles, with such other medicines as the peculiarities of the case may suggest. As the disease lapses into a subacute or chronic state, the warm or hip-bath, opiates with soap or alkalies, the infusion of *parira* or of *diosma*, the preparations of *cubebæ*, small doses of *copaiba* or of the other balsams, and the infusion or tincture of hops, may be severally prescribed.

90. The acute form of muco-cystitis will be protracted, or pass into the subacute, and ultimately into the chronic form, if the *regimen* and *diet* of the patient be not duly regulated. All spirituous, vinous, and malt liquors should be relinquished, as well as acidulated or sweetened drinks or fluids. The food ought to be farinaceous, demulcent, and vegetable, and prepared in as bland a form as possible. The drink should consist entirely of linned-tea, barley-water, or toast-water, gum-water, or marsh-mallow tea taken in moderate quantities.

91. In severe or obstinate cases some practitioners have recommended the injection of oil

and opium into the bladder by means of a gum-elastic catheter. As to this treatment, Mr. COULSON has very justly remarked, that the pain and irritation caused by the introduction of any instrument along the urethra are so severe as to deter him from resorting to this treatment; for, unless there be retention of urine, the use of the catheter, sounds, and bougies should be avoided.

92. *B. Treatment of Chronic Muco-Cystitis.*—This form of the disease is often complicated with stricture of the urethra, or with disease of the prostate or kidneys; and it often also is consequent upon the acute form of the disease, owing either to neglect or to the constitution of the patient. In all cases the treatment of this form of muco-cystitis is difficult, and more especially when it is complicated, and in the aged and cachectic. When the disease is simple, or consists chiefly of an abundant secretion of mucus (cystorrhœa), the decoction of pareira, or the infusion of buchu, with opium or morphia, or with the dilute phosphoric or nitric or nitro-muriatic acids, and the decoction or extract of uva ursi, are generally of service; but, where there are also much irritability and pain of the bladder, opiates given by the mouth or in enemata are most requisite, and should be conjoined with every other method of cure. Sir A. COOPER recommends the balsam of copaiba, in doses of eight or ten drops thrice daily, with mucilage, sweet spirits of nitre, and camphor mixture. Mr. COULSON advises small doses of copaiba, or of the essential oil of cubebs with hyoseyamus, either to be given alone, or with the infusion of buchu, or with the decoction of pareira. He adds, however, that both copaiba and cubebs should be given with care; for, after the prolonged use of these remedies, an aggravation of the disease may result. He frequently, therefore, gives the compound tincture of benzoin, in the dose of a tea-spoonful, three times daily; and, when the urine is alkaline, and contains much mucus with the phosphates, an infusion of the dried *Alchemilla arvensis* (one ounce to a pint of boiling water), the dose being two ounces of the infusion three times in the day. The muriated tincture of iron, the ammoniated tincture of iron, the balsams, Chio turpentine, and other kinds of turpentine, uva ursi, with camphor and nitre, the sulphates of iron and of zinc, have also been severally employed in this state of the disease, and are generally of service when aided by opiates, and when the digestive organs and bowels are duly regulated. DUPUYTREN relied much upon turpentine when the mucous secretion was great; and I have had occasion to observe its good effects; but it should not be long continued, although it may be given at intervals, or alternately with other means.\*

\* The *copaiba* is much employed in this country in cases of vesical catarrh, and often with decidedly beneficial effects. It should be given in moderate doses, as 10, 15, or 20 drops every four hours, in emulsion of gum arabic and sugar. If it gripes, nauseates, or purges, *tinct. opii* or *morphia* should be combined with it; and if pyrosis or acid eructations be present, bicarbonate of soda is a very useful adjunct. Its use must be continued in chronic cases several weeks, the patient using at the same time the fluid extract of *uva ursi*. If its taste become disgusting, *turpentine* may be substituted for it. We have in many cases used the *uva ursi*, in connexion with alkalies, with a successful result. The *chimiphila umbellata* is also very useful in this disease. The *epicaca repens* (May-flower) is extolled by Dr. IVES, of New Haven, as a highly useful remedy in this affection. A wine-

93. Persons of a scrofulous diathesis, or those addicted to venereal excesses, or who have suffered from syphilitic affections, or who are subject to hæmorrhoids or to gout, are liable, when they are attacked, to an obstinate form of this disease. For these the treatment should have more or less reference to the state of constitution, while the local affection also obtains sufficient attention. The aged and cachectic also require to have their constitutional powers supported while the urinary disease receives requisite care. But in these latter persons palliation alone can be hoped for; and the prolongation of life, by means of a restorative or tonic treatment, opiates, and a regulated diet, is often the whole amount of benefit that can be expected.

94. When chronic muco-cystitis is associated with stricture of the urethra, or is produced by it, the treatment is extremely difficult. Mr. COULSON remarks that "the pain and irritation along the urethra are often so great as to render the use of catheters and bougies impracticable: and, unless the state of the urethra improve, no material benefit can be expected from internal remedies." Under these circumstances, having calmed the pain and irritation by means of sedatives, he proceeds to dilate the urethra with bougies or the gum-elastic catheter; and, if the stricture be of long standing and very narrow, he commences with armed bougies, introducing them once in three or four days.

95. The frequency of this, as well as other forms of cystitis in the gouty, and even also in the rheumatic diathesis, and of the occurrence of the disease in connexion with, or upon the disappearance of gout, suggests the propriety of modifying the treatment conformably with this connexion. In these cases I have found the opium and soap pill, with the extract of colchicum, taken at bed-time, and a sufficient dose of magnesia and sulphur, or magnesia and rhubarb, early in the morning, to prove of great service. One or other of the other means already mentioned, avoiding the acids, may also be given in the course of the day, as circumstances may indicate.

96. Other means, which more especially belong to the province of the surgeon, have been advised in the more severe and protracted cases of muco-cystitis. Sir B. BRODIE states that when "the symptoms are at their greatest height, the mildest injections (into the bladder), even those of tepid water, will do harm rather than good. They are especially to be avoided when the mucus deposited by the urine is highly tinged with blood. When, however, the symptoms are abated, the injection of tepid water, or decoction of poppies, is, in many instances, productive of excellent effects." The fluid should be allowed to remain in the bladder about thirty or forty seconds, and not more than two ounces should be injected each time. Distention of the bladder by the injection so as to cause pain is injurious, and should be avoided. The operation may be repeated once or twice in the twenty-four hours. When the symptoms have abated and assumed a still more chron-

glassful of a decoction, made with two drachms to half a pint of water, is to be given every two hours. In its effects it is closely allied to the *uva ursi* and buchu (*Trans. Amer. Med. Assoc.*, vol. iii., p. 314). See also a paper by Dr. LA ROCHE on *copaiba* in this affection, in *Am. Jour. Med. Science*, vol. xiv. Dr. GROSS speaks very favourably of the *benzoë* acid, given alone, or in combination with bals. *copaiba*, in doses of 15 to 20 grs. three or four times a day, or with a few drops of Haerlem oil.]

ie form, and the mucus is free from blood, then one minim of the strong, or ten minims of the diluted nitric acid, to two ounces of distilled water, may be used as an injection; the proportion of the acid being afterward increased. Mr. COULSON remarks that the tenacious mucus produced in this state of the disease deposits phosphate of lime; and when phosphate of lime from this source coexists, as it often does, with the triple phosphate in the urine, a compound salt is formed; and in such cases a weak solution of nitric acid (beginning with one minim of strong acid, increasing the quantity to two, to two ounces of distilled water) injected into the bladder acts as a salutary stimulant. As to LALLENAND's cauterization of the mucous membrane of the bladder with solid nitrate of silver, in cases of chronic catarrh, and as to DEVERGIE's injections with balsam of copaiba and narcotics, I must refer the reader to the work of the author just mentioned, and to other surgical works.\*

97. It should not be overlooked that excessive mucous secretion from the surface of the bladder, if neglected, or treated too long with some of the more heating substances which have been advised, may be followed by a chronic inflammation of all the coats of the bladder, and ultimately by a subacute or an acute form of the disease, which may destroy the patient. This result is most likely to occur when the *diet* and *regimen* so requisite to the success of treatment have been neglected. In the milder form of the disease, animal food in very moderate quantity may be taken. The diet should be chiefly farinaceous, but the white kinds of fish, boiled, may be allowed.† In the severer states animal food should be still more sparingly taken. If in these the vital powers be much depressed, sufficient light nourishment may be given, and tonics with the alkaline carbonates, opiates, &c., may be prescribed. Spirituous, vinous, and malt liquors should be strictly prohibited, and all irregularity of diet and regimen carefully avoided. When there is great debility, dry

(\* Dr. GROSS (*loc. cit.*) recommends, in obstinate cases of this disease, *counter-irritation* in the form of a seton, issue, or tartar-emetic pustulation, over the perineum or the suprapubic region. If there is reason to suspect renal disease, the counter-irritation should be over the sacrum or in the loins by means of a seton, and the discharge kept up for a long time. When *irrigation* is practised, a better mode than that recommended is to use a double catheter, and gently inject a pint of tepid water, so as to wash out the bladder thoroughly; and it may be repeated twice a day, unless the urine is bloody, or there are symptoms of cystitis present. With regard to the various medicated injections for a local alterative effect on the mucous membrane, we greatly prefer a solution of the *nitrate of silver*, in combination with the fluid, watery extract of *opium* or *hyoscyamus*, beginning with a weak solution, and gradually increasing its strength, throwing in about two ounces each time, and allowing it to be retained from five to ten minutes; the patient placing himself in different attitudes to bring it in contact with every part of the bladder, and repeating the injection once a day, or every third day, according to circumstances.

Where every thing has failed, it has been proposed by Mr. GUTHRIE to open the neck of the bladder by an incision, as in lithotomy, so as to allow a free outlet to the mucous secretion as fast as it is poured out, and thus afford the bladder comparative repose; on the same principle as the knife is recommended for anal fistule and fissure. This operation has been performed by Dr. W. PARKER, of New York, with evident relief of the symptoms, but the patient succumbed four weeks after from organic dis ease of the kidney and bladder. (See *New York Journ. of Med.*, 1850.)

[† We have generally found an entire abstinence from animal food the preferable course, and only allow mild broths when convalescence is fully begun. *Vegetable acids* are always prejudicial in this disease.]

sherry may be allowed, especially if acidity of the *prima via* be not experienced. In all cases the functions of the skin as well as of the bowels should be duly promoted.

98. *C. Treatment of Acute Cystitis—of Acute Inflammation of all the Coats of the Bladder* (§ 56).—It has been above (§ 55) stated that the inflammation may affect one of the tissues of the bladder more than the others, or may implicate them all, chiefly through the medium of the connecting cellular tissue, and that a portion of the bladder may be thus affected, or the whole of the organ; that when the inflammation is seated in the neck of the bladder, the urine is retained by the tumefaction occasioned by it; and that when the parts through which the ureters pass into the bladder are chiefly affected, the swelling which results more or less obstructs the passago of the urine, and occasions dilatation of the pelvis, ureters, &c., by its accumulation in these parts and suppression of this excretion. The consequences of the *retention* on the one hand, and of the *suppression* on the other, are always most serious, and should be prevented by a most active treatment as soon as these important and always dangerous states are present. The former may be removed by surgical aid; the latter by prompt and judicious medical treatment. But in most cases the treatment should have reference to the cause of the disease and the diathesis of the patient. When the malady is produced by cold in any form, then the phlogistic form may be inferred, and suppuration may take place, especially in the phlogistic temperament and full habit of body. When it is occasioned by spirituous liquors, aphrodisiaes, or the suppression of the gonorrhœal discharge, although all the coats may be implicated, the mucous wall generally be chiefly affected, and retention or suppression of urine less frequently result. If the disease occur in the gouty or rheumatic diathesis, or follow upon suppression or metastasis of either gout or rheumatism, all the coats may be affected, and neither the fundus nor its peritoneal covering escape.

99. In all these circumstances the treatment should be prompt and decisive, and the quantity of urine retained in the bladder carefully watched, by examining the hypogastrium and the quantity excreted. If the patient be young, or robust, or plethoric, although advanced in life, venæsection should be prescribed and even repeated, and be followed by the local depletions, which may be sufficient for the delicate or weak, by cupping on the perineum, or by leeches applied to the part or to the pubes. Hot baths; warm fomentations above the pubes or on the perineum; the removal of the urine by means of the catheter whenever it may be required; emollient, laxative, and anodyne injections; cooling saline aperients, preceded by calomel and opium when the febrile symptoms are severe and the biliary functions are impaired; and demulcents with diaphoretics—are the means of cure which may be safely resorted to in all the circumstances of the malady just noticed. If the disease be consequent upon gonorrhœa, oleaginous or mucilaginous demulcents, with small doses of camphor, nitrate of potash and henbane, in addition to appropriate depletions, diaphoretics, aperients, &c., will generally remove the more urgent symptoms. If it be connected with gout or rheumatism, magnesia and sulphur in equal parts, either alone or with demulcents, and small doses of colchicum, will

be found very beneficial, by moderately promoting the abdominal secretions and the functions of the skin; this latter being too generally overlooked, especially in gouty affections. Under the above treatment the symptoms generally subside gradually; but if retention of urine be long neglected, or if the urine be suppressed, owing either to delay in adopting the above means, or the constitution of the patient and violence of the attack, delirium, coma, and death will generally result. It may be asked, What should be done in cases where the urine has become suppressed? I would answer, after the above means have been judiciously employed, that warm flannels, or stupes, moistened with spirits of turpentine, should be applied over the hypogastric region and perineum, and that emollient enemata, containing equal parts of this substance and castor oil, and one or more ounces of olive oil, be administered and repeated as they may be required, while diaphoretics should be assiduously continued.

100. When the inflammation of the fundus of the bladder implicates the peritoneal coat, or is associated with inflammation of the uterine organs or peritoneum, the treatment is not then materially different from that recommended above. Cupping over the sacrum, leeches to the hypogastrium, &c., the warm terebinthinate embrocations, or stupes, in these situations, calomel and opium, followed by the enemata and diaphoretics already advised, are the means most generally appropriate.\* If cystitis be complicated with hæmorrhoids or inflammation of the rectum or colon, or with fistula, calomel should be withheld, as it generally increases these affections, and thereby prevents the resolution of the uro-cystitis; but the other means ought to be employed.

101. *D. Treatment of Chronic Uro-Cystitis.*—Chronic uro-cystitis is often consequent upon the acute, but it is oftener a consequence of stricture of the urethra, of enlargement of the prostate, of stone in the bladder, of prostatic calculi, of the abuse of spirituous liquors, especially of common gin; of the use of cantharides, or of cubebæ or copaiba; or protracted gout and rheumatism, especially the former; and of the retention of the urine in the bladder after the desire to pass it. The nature of the cause influences more or less the treatment to be adopted. In strong, young, or plethoric subjects, and especially when considerable pain is experienced, local depletion, followed by warm baths, the semicupium, fomentations, &c., is always required. In many cases the removal of the primary disease should be the first indication, especially in the case of stricture of the urethra; and with this indication the employment of means which act more or less directly on the bladder should also be adopted. In most instances the selection of these means should be guided by the state of the urine. If this be acid or scanty, the bicarbonates of the fixed alkalies with nitrate of potash and sweet spirits of nitre, in demulcent or emollient vehicles, will be generally of great service; and anodynes, such as the sirup of poppies, tincture of henbane, compound tincture of camphor, tincture of hop, opiate suppositories, &c., will also be prescribed in many cases with advantage. The preparations of pareira brava, or of the diosma, or of uva ursi [or *Epigea repens*, or *chimiphila umbellata*] may, in the more obstinate or chronic cases,

be given with the above, or the decoctions or infusions of these latter may be the vehicles for the exhibition of the former. When the disease occurs in the gouty or rheumatic diathesis, or appears after the suppression of either of these diseases, then the extract, tincture, or wine of colchicum in small doses, may be prescribed with the alkalies, and a small dose of opium or of morphia; and when the pulse presents much strength or hardness, the tincture of aconite, in the dose of one, two, or three drops, may be resorted to, although this latter is more appropriate in the more acute cases, and when the peritoneal covering of the viscus is implicated in the disease. The infusion of parsley-root is sometimes of service in chronic uro-cystitis, especially when made the vehicle for some of the medicines mentioned above. Mr. COULSON states that he has tried the infusion of wild-carrot seeds in this form of the disease with advantage, but that it should not be given if there be any irritation of the mucous membrane; and he adds that, as in these cases the bladder is, by its own efforts, seldom completely emptied, a catheter should be introduced from time to time, and the patient be instructed to do this for himself. Unless this direction be strictly attended to, the patient will become worse, and serious consequences ensue.

102. *E. When inflammation is extended to the peritoneal coat of the bladder*, either from the internal coats, or from parts in the vicinity of, or in contact with the peritoneal, the symptoms may then be very acute, and become chronic from neglect or injudicious treatment. This form of the disease is most frequent in females, especially after parturition or in some period of the puerperal state, and is generally contingent upon the occurrences which sometimes take place during this state. In some cases it is strictly a partial peritonitis, confined chiefly to the pelvic peritoneum; the symptoms, local and general, being distinctive of its nature and seat. (See art. PERITONEUM, *inflammation of*, § 76.) The seat of pain, tenderness, and tension, the rapidity of the pulse, the position of the patient, the expression of the countenance, &c., indicate the nature of the disease, which may be limited to the pelvic peritoneum, especially when coagulable lymph is thrown out, which forms adhesions between the opposite surfaces, and prevents the extension of the malady. In unhealthy constitutions, and in females in the puerperal states, the inflammation, instead of being thus limited, generally extends over the peritoneum; in place of coagulable lymph, a serous fluid, of varied appearances, is thrown out, and the morbid action, commencing in the hypogastric region, extends through the abdomen, which becomes tender and tympanitic. The pulse is so rapid as hardly to be counted; hiccough supervenes, and the disease presents the course and termination described in the article PERITONEUM (§ 19–36). In these cases the treatment is the same as I have advised in that article (§ 137–159, *et seq.*).

103. In rare instances an abscess forms below the peritoneum, between the bladder and the symphysis pubis, or some other adjoining part, as in a case related by Dr. ELLIOTSON. Sometimes also a pseudo-abscess is seated within the pouch of the peritoneum, between the posterior wall of the bladder and the rectum. Lymph, in these cases, agglutinates some folds of the intestines, or the sigmoid flexure of the colon and the fundus

\* Anodyne suppositories are better suited to this disease than enemata.]

of the bladder, and pus collects in the pouch formed by these parts. The contents of this pseudo-abscess may be absorbed, if in small quantity, old adhesions alone remaining; or they may find their way into the peritoneal cavity, and occasion general peritonitis and death. Cases of this nature are mentioned by Mr. COULSON, and they have been seen by myself, but only in females, and as consequences of pelvic peritonitis after parturition (see *art. PERITONEUM*, § 76, *et seq.*, and *PUERPERAL DISEASES*, § 221, *et seq.*).

104. V. MALIGNANT AND OTHER FORMATIONS are sometimes found in or attached to the parietes of the urinary bladder.—*A. Tubercle* is occasionally deposited in the parietes of this viscus, generally either under the peritoneal coat, at the fundus, and in the mucous membrane, near the urethra. In this latter situation the small granular deposits pass rapidly to ulceration. Tubercle of the vesical mucous membrane is, according to ROKITANSKY, rare, and is not always formed in connexion with tubercular affections of the urinary and sexual organs. Tubercle on the exterior of the bladder is generally seen associated with the same formations in the vicinity, especially in the female sexual organs. Mr. COULSON remarks that the morbid deposit may be so great as to glue together the different organs, and thus interfere with the free action of the detrusor urinae; but this can only occur when the tubercular cachexia is inordinately developed. The most frequent appearance of tubercle in connexion with the bladder is in cases of tubercular peritonium, that part of the membrane covering the bladder partaking in the general alteration, the deposit being commonly in small distinct masses, the membrane being spotted, dark-coloured, or rugous, or otherwise altered. (See *PERITONEUM*, § 111, *et seq.*)

105. *B. A polypous excrescence* from the internal surface of the bladder is very rarely observed. Dr. BAILLIE saw only one example of it, and that filled up the greater part of the cavity of the viscus. An instance of it occurred to Mr. CROSSE, of Norwich, in a child. Other cases of polypus vesicae have been recorded by Mr. WARNER and others, but they require no particular notice. The very interesting and instructive case published by the late Mr. CROSSE will be found in Mr. COULSON's work.

106. *C. Malignant formations* in the bladder are not very rare. The worst form is that described by Mr. TRAVERS and others as the malignant medullary fungus, which arises from the sub-mucous tissue, and projects into the cavity of the viscus as a soft, vascular, and cauliflower-like mass, which bleeds upon the slightest touch. Mr. TRAVERS states that it springs from "the mucous coat of the bladder, and resembles that of the nares and uterus, breaking, bleeding, and reproduced as quickly as it is displaced. It is of very extensive attachment, and gradually reduces the cavity to very small dimensions. Portions of fungus and coagula of blood become plugged in the urethra, and form firm pellets, so as to produce retention of urine. It is a very painful disease. It keeps the patient in constant anxiety to void urine, which is more or less tinged with blood, and frequently he passes blood alone. He dies hectic and wasted." Mr. COULSON states that this malignant fungus is generally first developed near the neck of the bladder, the trigon, or the posterior surface; and that cases occur in

which the vegetations fill a diverticulum or sacculus, where they form a tumour which may cause retention of urine by its pressure. These tumours vary in size, some being, when solitary, as large as a goose's egg; others are small, especially when they are numerous. Another form of medullary cancer has been described by ROKITANSKY as occurring in small masses between the muscular and mucous coats of the bladder. It may make its way through the mucous coat and form a deep carcinomatous ulcer, or may protrude externally through the muscular and peritoneal coats. Fibrous or scirrhous cancer, although sometimes affecting the uterus and ovaries, very rarely attacks the urinary bladder. These malignant formations cannot be assigned to any local cause of irritation, or to any other cause beyond the cancerous diathesis, hereditary or acquired. (See *art. CANCER*, § 23, *et seq.*)

107. *a. The symptoms* of malignant tumours of the bladder frequently resemble those of stone. WARREN states that the first sign of this disease is a discharge of blood with the urine. The quantity is at first so small as scarcely to tinge the urine, but it gradually increases until it becomes an exhausting symptom. The amount of pain attending it varies in different cases, being slight or moderate in some, and severe in others. Constant desire to pass urine is one of the most common symptoms, accompanied with sympathetic irritation of the rectum and inclination to stool. When blood passes from the bladder after the introduction of a sound or catheter, or after the flow of urine has terminated, or very nearly terminated, there is much reason to infer that it proceeds from the coats of the bladder; and when this occurs in connexion with the other signs, and especially with the sense of the existence of a body or substance in the bladder, felt either by the patient or the operator when a sound is introduced, the existence of a malignant tumour, fungus, or polypus may be inferred. Ultimately, in these cases, consecutive disease and disorganization of the kidneys, with more or less marked disorder of the stomach and bowels, and exhaustion of the powers of life, is followed by a fatal issue. I may refer the reader to Mr. COULSON's work for some instructive cases and *post mortem* appearances of this disease.

108. Disease of a disorganizing nature may extend to the bladder from malignant disease of the rectum in men, or of the womb in females; and by means of ulceration a communication may be established between the rectum and the bladder, or between the bladder and vagina.\* Mr. TRAVERS, however, doubts whether the ulceration of the bladder in these cases be truly cancerous. In this doubt Mr. COULSON appears to partake. I have seen a few cases of extension of malignant disease from the neck of the uterus to the bladder, but in most of them have had reason to infer that the disease in the latter partook of the same character as that of the former.

109. *b. The treatment* of malignant disease of the urinary bladder is chiefly palliative, by means

\* The mode of treatment by *suture*, in cases of vesico-vaginal fistula, has been in vogue since the 17th century; but the profession is under great obligations to Dr. J. M. SIMS, of New York, for his improvement of the ordinary operation, which is sufficiently easy, simple, and safe, and in a very great degree successful. For a full description of his mode of procedure, see *New York Medical Gazette*, vol. v., 1854; *American Medical Monthly*, Feb., 1854; and GROSS on "Diseases of Bladder," p. 156.]

of narcotics, sedatives, &c., administered by the mouth, or in enemata, or in suppositories, as advised when treating of CANCER, and of diseases of the UTERUS, &c. In many of these cases the hæmorrhage from the bladder is so excessive that means are required to arrest the discharge and to sustain the powers of life. For these the tincture of the sesquichloride of iron, the decoction of pareira brava, with nitric, or hydrochloric, or sulphuric acid, if the urine be alkaline; the uva ursi, with the alkalies, if the urine be acid; the secale cornutum, spirits of turpentine, and other anti-hæmorrhagics and astringents, the recumbent posture, &c., are the means chiefly to be confided in, conjoined with opiates, &c.

110. VI. ABNORMALITIES OF THE BLADDER are sometimes observed, either alone or in connexion with malformation of other parts of the urinary or sexual organs. They are generally congenital, and proceed from irregularities of fetal development. Numerous cases and various forms of irregularity of formation are on record; but as respects any treatment which may be adopted for them, they concern the surgeon more than the physician, and sufficient reference may be made to them in the subjoined Bibliography.

111. *Foreign bodies* are often found in the bladder, having been introduced at some previous period, or having passed into it from the rectum or some part of the intestinal canal, through a perforating ulcer or sinus formed between the bowel and bladder.\* In many instances, when a foreign body has been found in this viscus, it had become incrustated by the urinary deposits to a greater or less extent. This subject will be found more appropriately discussed in surgical works, where also *rupture of the bladder*, *hernia of the bladder*, and *wounds and injuries of the bladder*, are most ably treated of by their respective authors.

\* *Worms*, chiefly of the *ascariidæ* genus, have not unfrequently been found in the human bladder, having crept thither from some part of the intestinal canal, either by perforating its coats or through some ulcerous opening. Mr. LAWRENCE and T. B. CURRIE, of London, have both described instances of this kind (*Medical Clin. Trans. of London*, vol. ii., p. 385, and vol. xxii., p. 279); and in this country, among several others, Dr. BARDWELL, of Indiana (*West. Journ. of Med. and Phys. Sci.*, vol. vii., 1834), and Dr. CAMPBELL, of Conn. (*Am. Journ. of Med. Sci.*, vol. xxi., p. 130). In the former case, many thousand worms were passed in the course of six months, of a lumbricoid kind, from six to nine lines in length, and about the thickness of a horsehair, with a black and rather large head, the body of a dark, dirty white. Some of them lived 24 hours after they had been voided. The patient, a man aged 30, recovered under the use of turpentine. In the latter case the worms were small, red-headed, and about half an inch long, the bodies composed of many minute cartilaginous rings, and furnished with a number of legs, arranged in two rows from one extremity to the other. They were hard, very active, strong, and tenacious of life. See also a case in Dr. GROSS's work, so often quoted (p. 332, 2d ed.), with a history of symptoms, treatment, and all there is known on the subject.]

## URINE AND ITS DEPOSITS.—CLASSIF.—

### GENERAL AND SPECIAL PATHOLOGY, AND THERAPEUTICS.

1. The urine is one of the chief depurating secretions in the animal economy, and one which, when interrupted or arrested, rapidly terminates existence. This secretion in some form or other occurs in all animals, either by a distinct apparatus, or by a vicarious or associated function, in which latter form it also takes place even in the vegetable creation; and in all it is characterized as the excretory function of nitrogenous elements and compounds, variously associated with other substances. In the human subject and in the more perfect animals the conditions of the urine depend upon the states of the frame generally, upon the states of the urinary organs, and upon the food and drink of the individual. Hence these conditions are of the greatest importance to the pathologist, by enabling him to recognise, 1st, those states of the system with which they are severally connected; 2d, those lesions, functional and structural, of the kidneys, of which they are often the symptoms and effects; and, 3d, the influences produced by the food and drinks of the individual upon his system and urinary organs.

2. The urine is derived from the blood—is a depurating secretion performed by the kidneys from the blood as long as these organs are actuated by the organic nervous influence distributed to them, aided by whatever share of influence may

be transmitted to them or their ganglia by the spinal nerves. The urine being derived from the blood, and being one of the chief depurating secretions by which the blood is preserved in due or healthy quantity and quality, it must be manifest that the phenomena connected with the urine and its secretion become important indications, not merely of the states of the blood itself, but also of the several sources by which the blood is altered or contaminated.

3. It was stated in the first part of this work, and then explained (in 1832), that the kidneys conveyed from the blood the fluids carried into the blood, and with these fluids the effete materials, the ultimate results of animalization, and various other elements and substances resulting from indigestion and mal-assimilation, or otherwise absorbed into the circulating mass. As long as the kidneys discharge their functions, an excess of the fluid elements of the blood, and of various saline and nitrogenous materials, are prevented from accumulating in the blood; these functions being strictly depurating, as respects the purity or quality of the blood, and eliminating, or excretory, or excrementitious, as respects not only the quality but also the quantity of the circulating mass.

4. It is thus obvious that the urine consists chiefly of the fluids and of the fluid parts of the aliments taken into the stomach, and carried into the blood; and that it contains not only saline and other ingredients derived from the ingesta, and from the changes which the ingesta undergo, in the digestive canal, and in their passage into the blood, but also the effete nitrogenous materials resulting from the waste and absorption of the tissues, which are first conveyed into the blood by the absorbents and veins, and afterward eliminated from the blood, with the fluids in excess, by the action of the kidneys.

5. Such being the source of the urine, it may be inferred that the quantity and condition of this excretion will depend upon a variety of circumstances which require the recognition of the pathologist in his investigations of disease—upon the states of the digestive and assimilating functions; upon the states of the circulating organs and of the blood; upon the states of the urinary apparatus; and upon the states of the other depurating and eliminating functions—upon those of the skin, lungs, liver, and intestines. In recent times, and in recent writings, the conditions of the urine have received a due, if not an excessive, share of attention, especially from the chemical pathologists; yet these conditions have been insufficiently investigated in their relations to the other depurating functions, and especially to that of the skin, this particular function being either altogether overlooked, or very imperfectly inquired into. When treating of the Blood (see § 115–160), and when giving a succinct view of pathology under the head of DISEASE (see § 94–104, and 163, *et seq.*), I there stated the same doctrines as those now enunciated, but more explicitly and fully than I have now done; and since then (published in 1832) the same views have received the approval of, because they have been altogether adopted by, more recent writers, although without acknowledgment of their long previous existence in the pages of this work. I may request those who are curious in this matter to read what I have stated in the articles and in the sections just referred to, and to peruse the

fundamental doctrines in Dr. GOLDING BIRD'S work on "*Urinary Deposits*," where the subject of urinary pathology has been very ably discussed, and where not only the views, but even the terms, first adopted by me have been followed and employed. I should not have referred to these principles of urinary pathology if it had not been necessary, by asserting my own priority in respect of them, to defend myself from the contingent imputation of adopting the ideas of others.

6. *b.* The doctrines insisted upon in the early parts of this work respecting the depurating functions of the kidneys and of other organs, have been much more recently carried out by Dr. G. BIRD, as regards those of the kidneys, and in many places so conformably with these doctrines—although with too manifest a leaning to chemical pathology and neglect of a controlling vital influence—as to induce me to refer to his evidence on several topics, where I believe it to be accurate, or to support my own views. The fundamental principle he has laid down is correct as far as it extends, but it is too limited, inasmuch as it is confined to the functions of the kidneys. He states that "it is, indeed, a general law, that any substance which has entered the circulating mass, and not been required for the nutrition of the body, nor forming a normal element of healthy blood, always escapes from the system by the kidneys, providing it exists in a state of complete solution. Hence these most important emunctories have the duty of removing any imperfectly assimilated elements of the food which had been absorbed while traversing the small intestines, and entered the circulating mass, as well as excreting the often noxious results of unhealthy digestion. To effect these most important conditions, it is essential that the substance to be removed should be soluble, or at least capable of being readily metamorphosed into a body soluble in the water of the urine, as nothing can be excreted from the kidneys, without breach of surface, unless in a state of solution. The third function performed by the kidneys is their serving as outlets to evolve from the animal organism those elements of the disorganization of tissues which cannot perform any ulterior process, nor be got rid of by the lungs or skin. The disorganization of tissues here alluded to is a necessary result of the conditions for the growth and reparation of the body." "The old and effete atoms of the animal structure are not excreted in the form of dead tissue, but, becoming liquefied, they re-enter the circulation, their elements being rearranged. One series of combinations thus produced, rich in nitrogen, is excreted by the kidneys, while those products which contain a preponderance of the inflammable elements, carbon, hydrogen, and sulphur, are called upon to perform, chiefly through the medium of the liver, an important office previous to their final elimination from the system. Thus the blood is not only the source of the elements derived from the food which serve for the nutrition of the body; but it also serves, like a sewer, to receive the matter arising from the waste and liquefaction of the old and exhausted tissues." (P. 256.)

7. Now all the ideas contained in this quotation will be found fully and explicitly stated, as referred to above (§ 3-5) and in other places, but more correctly and more conformably with pathological conditions than in the above passage, in the *first volume of this work*, published many

years before the appearance of "*Urinary Deposits*." Besides, Dr. G. BIRD has overlooked the functions of the skin in relation to those of the kidneys, and has not taken a correct view of those of the liver in connexion with the functions of the lungs, while those of the follicular apparatus of the intestinal canal and of the skin have been altogether neglected. Yet all these functions, as I have elsewhere shown (see the articles BLOOD, CRISES, DISEASE, and EXCRETIONS and EXCRETING FUNCTIONS, &c.), are more or less intimately related to each other and to the depurating functions of the kidneys, and often evince, even in health, a vicarious increase when one or more of the others are impeded or diminished, and a marked diminution when they are augmented. It should also be recollected, when estimating the source and nature of the functions of the kidneys and of other eliminating organs, that it is not only the materials mentioned in the above quotation which are eliminated from the circulation by the kidneys, but also a portion of those resulting from the waste of the red globules and fibrin of the blood, and that the kidneys are not the only depurating organs, the functions of the skin, liver, bowels, &c., being generally more or less impaired or otherwise disordered in those diseases which evince the most remarkable alterations in the state of the urine, these functions, especially that of the skin, being too generally neglected by modern physicians in favour of the popular attractions furnished by the functions of the kidneys.

8. It is obvious, from what I have stated now and in earlier parts of this work respecting the sources of the urine, that this depurating secretion will vary in quantity and sensible appearances and physical properties, and even be remarkably altered, by a variety of causes—1st, by the quantity and nature of the ingesta, alimentary and liquid; 2d, by the imperfect and disordered products of indigestion and mal-assimilation resulting from impaired vital power or simple or complicated ailments; 3d, by the metamorphosis and waste of the several tissues and of the blood—the removal of effete materials into and from the blood—during the healthy processes going on throughout the frame; 4th, by the waste and metamorphosis of the structures and of the blood, when accelerated by local or constitutional diseases; 5th, by the absorption of morbid secretions, and deposits or formations carried into the blood, and partially, chiefly, or altogether eliminated by the kidneys and other emunctories; 6th, by the varying states of the other depurating functions—by the increase and diminution of one or more of these, diminishing, increasing, or altering more or less the functions of the kidneys.\*

\* "In morbid states of all the principal organs the urine is remarkably liable to change. This arises from various causes. If the stomach be the primary seat of disease, or if its condition be disturbed through sympathetic influences of other diseased organs, as is almost constantly the case, digestion is imperfectly performed, and the chyle, in consequence, becomes more or less unfitted for the purposes of nutrition and secretion. The kidneys, therefore, carry off more than their wonted quantity of excrementitious matter, while this matter appears under conditions more or less varied from the natural product. The whole office of appropriation is, also, more or less impaired, which farther modifies the condition of the blood and the formative action of the kidneys; though a part of the office of excretion, under these circumstances, devolves upon the skin and lungs. A great cause of the variability of the urine consists in unusual vital decomposition or wasting of the body, or of some of its parts, when it devolves upon the kidneys

9. Dr. PROUT considered that the elements of the albuminous tissues of the frame are so arranged, during the processes of metamorphosis or waste, as to be converted into uric acid, or urate of ammonia, and that the atoms or elements not composing these bodies form certain ill-defined principles. The ulterior changes which the gelatinous tissues undergo during destructive assimilation this very celebrated physician supposed to be intimately connected with their conversion into urea, and some saccharine principle, or its close ally, the lactic acid. BARON LIEBIG followed in the path pointed out and first trodden by Dr. PROUT, and has been in several matters supported by the researches of MULDER, TAYLOR, B. JONES, and others. According to LIEBIG's theory, the elements of muscular tissue are carried into the circulation, combined with water and oxygen; the latter, by its union with the carbon of the effete tissue, supports the temperature of the body. On reaching the structure of the liver, 50 atoms of carbon, 1 of nitrogen, 45 of hydrogen, and 10 of oxygen, with an unascertained but considerable proportion of sulphur, are filtered off from the portal blood in the form of bile. The more highly nitrogenized elements of the metamorphosed or wasted tissues are separated by the kidneys from the blood, chiefly in the form of urea and uric acid, while the carbonic acid formed by the slow combustion of the carbon of the original atoms of muscle in the capillaries is exhaled from the surfaces of the skin, and bronchi, and air-cells.

10. It is manifest that the atoms or elements of tissues, which have become worn out, or which have given place to new deposits in the course of nutrition, are carried into the circulating mass, where they undergo progressive changes under the influence of vitality, and are ultimately eliminated from the blood by the depurating organs. It has been supposed that the states in which the several materials are found on their elimination are such as may be altogether imputed to the action of the excreting organs; but it is more probable that the atoms or elements composing the

to co-operate, beyond their natural habit, with the lungs and skin, in removing the redundancy of waste materials. A fourth cause of the urinary changes, and an important one, lies in actual morbid states of the kidneys themselves. The kidneys, however, are not often the seat of morbid affections beyond those of a simple functional and transient nature, as induced by sympathetic influences exerted by the diseases of other parts, but to which influences the kidneys are extremely liable, and therefore to consequent modifications of the urinary product. Briefly, then, every alteration of the natural action of the kidneys, whether primary or sympathetic, and every defect in assimilation and appropriation, is attended by some change in the urine; while an endless variety is imparted to it by the qualities and quantities of the ingesta. From this circumstance, which should have prompted other conclusions, has arisen the belief that the state of the urine supplies some of the most important signs of pathological conditions, not only of the kidneys themselves, but of remote organs with which they may sympathize. From HIPPOCRATES to our day, elaborate disquisitions have appeared concerning the changes of the urine as indicative of particular forms of disease, of their special seats, of the different stages of their rise and decline, and of their degrees of severity and danger. The humoralists were apt to regard the unusual conditions of this product, and other "vitiated secretions," as the disease itself; and in this respect they are imitated by the humoralists of the 19th century. Chemistry has been also brought to bear upon the fluctuating states of the urine, and has increased the factitious importance of a symptom which is often as likely to denote some alimentary substance, or diverse forms of disease, or imperfect digestion, or some remedial agent, as the source from which it emanates."—*The Institutes of Medicine*, by Martyn Paine, 8vo, N. Y., 1847.]

materials removed from the structures, as well as those composing the blood, more especially the albumen, fibrin, red globules, and even the saline ingredients, undergo a succession of changes or modifications during their circulation through the body, until the great or ultimate change is produced by the organs which discharge them from the economy. It is not, however, conformable to the laws of the human frame that each organ should perform so simple and definite a function as the chemical pathologists believe. The skin certainly exhales carbonic acid; but it also discharges other materials by means of its follicular apparatus; while the bowels, chiefly by the same or a similar apparatus, also excrete effete materials from the circulation; and, although the combinations which are found during their elimination may be viewed as chemical, they are the results of vital action in health, are more or less modified in disease, and are such as rapidly undergo farther changes after their discharge, or after death, which changes are more decidedly chemical, and such as their individual elements chemically dispose them to assume.

11. I. IN HEALTH, the urine presents certain conditions, *a.*, especially as respects *specific gravity*, at different periods and in different circumstances. These have been distinguished into, *first*, the urine which is excreted shortly after drinking freely of fluids, the nature of the fluids modifying the appearances and odour of the secretion. This (the *urina potus*) is generally pale, and of a specific gravity varying from 1.003 to 1.010. *Second*, the urine secreted shortly after the digestion of a full meal (*urina chyli*), varying in physical characters with the nature of the food, and other circumstances, and presenting considerable density, its specific gravity varying from 1.020 to 1.030. *Third*, the urine passed after a night's rest (*urina sanguinis*): this is of intermediate density, and varies from 1.015 to 1.025. In order to ascertain the specific gravity of the urine, in health or in disease, the portions passed before retiring to rest, and on rising in the morning, should be separately tested by the urinometer, and the average density of the two will be a near approach to accuracy. Dr. PROUT assigned 1.020 as the average gravity of healthy urine. M. BECQUEREL stated that it is 1.0189 in men, and 1.0151 in women, the mean in both sexes being 1.017; and Dr. ROYER that the average of 18 healthy cases gave a specific gravity of 1.021.

12. The specific gravity of the urine at different periods of the day varies in disease, as well as in health, although in a less marked degree, and in some diseases more than in others; but this part of the subject has not been sufficiently investigated, and it is, moreover, liable to many sources of fallacy, as emotions of the mind, articles of diet, the beverages or drinks employed, the medicines taken, &c., all combine to render the results of observation uncertain. The nature, the stages, states, and course of disease, as of hysteria and other nervous disorders, febrile diseases, &c., also remarkably increase the difficulty.

13. *b.* The *quantity* of urine passed in the 24 hours, as well as its density and ingredients, varies very much in health, but still more remarkably in disease. The quantity and quality are modified by temperature, by exercise, by the functions of the skin, &c., by modes of living, clothing, &c. Dr. PROUT estimated the quantity at

30 to 40 ounces in the 24 hours. Dr. ROUTH found the average of 18 cases to be 35 ounces. M. BECQUEREL considered the quantity to be 43 ounces in men, and 47 in women, the general use of soups and weak sub-acid wines in France being productive of the increased discharge; but among the beer-drinkers of this country the amount given by Drs. PROUT and ROUTH would be found much below the average.

14. *c.* The quantity of the urine is, however, no measure of the depurating actions of the kidneys; for 20 ozs. of urine in the 24 hours may carry off as much *solid materials* as 40 ozs. at a different time or in a different person; for a density of the former amounting to 1·030 will furnish an equal quantity of those materials to those afforded by the latter at 1·015. Dr. DAY has shown that the formula for calculating the solids contained in the urine given by Dr. CHRISTISON is the most correct; and the following table, calculated from it by Dr. G. BIRD, will show at a glance the quantity of fluid and of solids existing in 1000 grains of urine of different densities. The gravimeter having shown the specific gravity, the proportion of solid matter is at once indicated by this TABLE:

TABLE I.

Sp. Gr.	Solids.	Water.	Sp. Gr.	Solids.	Water.
1001	2·33	997·67	1021	48·93	951·07
1002	4·66	995·34	1022	51·26	948·74
1003	6·99	993·01	1023	53·59	946·41
1004	9·32	990·68	1024	55·92	944·08
1005	11·65	988·35	1025	58·25	941·75
1006	13·98	986·02	1026	60·58	939·42
1007	16·31	983·69	1027	62·91	937·09
1008	18·64	981·36	1028	65·24	934·76
1009	20·97	979·03	1029	67·57	932·43
1010	23·30	976·70	1030	69·90	930·10
1011	25·63	974·37	1031	72·23	927·77
1012	27·96	972·04	1032	74·56	925·44
1013	30·29	969·71	1033	76·89	923·11
1014	32·62	967·38	1034	79·22	920·78
1015	34·95	965·05	1035	81·55	918·45
1016	37·28	962·72	1036	83·88	916·12
1017	39·61	960·39	1037	86·21	913·79
1018	41·94	958·06	1038	88·54	911·46
1019	44·27	955·73	1039	91·87	909·13
1020	46·60	953·40	1040	93·20	906·80

15. By measuring the quantity of urine passed in a given time, the weight of solids excreted by the kidneys may readily be calculated by means of the foregoing and the following tables, a pint of distilled water weighing 8750 grains. The following table is given by Dr. G. BIRD:

TABLE II.

Specific Gravity.	Weight of one Pint.	Specific Gravity.	Weight of one Pint.
1010	8837 grains.	1022	8 51 grains.
1011	8846 "	1024	8960 "
1012	8855 "	1025	8968 "
1013	8863 "	1026	8977 "
1014	8872 "	1027	8986 "
1015	8881 "	1028	89 5 "
1016	8890 "	1029	9003 "
1017	88 8 "	1030	9012 "
1018	8907 "	1031	9021 "
1019	8916 "	1032	9030 "
1020	8925 "	1033	9038 "
1021	8933 "	1034	9047 "
1022	8942 "	1035	9056 "

16. It may readily be calculated from these tables, that if 1000 grains of urine, of the specific gravity of 1·020, hold 46·6 grains of solid matter in solution (Table I.), a pint of the same specific gravity, weighing 8925 grains (Table II.) will hold 415·9 grains solid matter; and that, if two pints and a half of urine be passed, 1039·72 grains will be discharged in the 24 hours. Dr. GOLDING BIRD has calculated from Dr. CHRISTISON'S

formula a very useful table for showing the number of grains of solids in, and the weight of, a fluid ounce of urine, of every density, from 1·010 to 1·040.

TABLE III.

Specific Gravity.	Weight of one fluid Ounce.	Solids in one fluid Ounce.	Specific Gravity.	Weight of one fluid Ounce.	Solids in one fluid Ounce.
1010	441·8	10·283 grains.	1025	448·4	26·140
1011	442·3	11·336	1026	449·8	27·188
1012	442·7	12·377	1027	449·3	28·265
1013	443·1	13·421	1028	449·7	29·338
1014	443·6	14·470	1029	450·1	30·413
1015	444·0	15·517	1030	450·6	31·4·6
1016	444·5	16·570	1031	451·0	32·575
1017	444·9	17·622	1032	451·5	33·663
1018	445·3	18·671	1033	451·9	35·146
1019	445·8	19·735	1034	452·3	36·831
1020	446·2	20·792	1035	452·8	37·923
1021	446·6	21·852	1036	453·2	38·014
1022	447·1	22·918	1037	453·6	39·104
1023	447·5	23·981	1038	454·1	40·206
1024	448·0	24·951	1039	454·5	41·300

17. By multiplying the number of ounces of urine passed in the 24 hours by the two last figures of the specific gravity, the quantity of solids excreted will be obtained. Thus, if three pints, or 60 ounces, be discharged in the 24 hours, and the density of the several specimens give an average of 1020, the 60 ounces multiplied by 20·79 would give a product of 1247 grains, the quantity of solids excreted in the 24 hours. Dr. G. BIRD estimates the average amount of solids excreted by the kidneys of the healthy adult to be from 600 to 700 grains in the 24 hours; numerous circumstances connected with occupation, exercise, diet, regimen, &c., modifying the results.

18. *d.* The tints presented by the urine in different diseases are of great importance in respect both of diagnosis and of treatment. These tints vary with the degree of dilution and the nature of the ingredients from nearly colourless, to the usual pale amber colour, to deep brown. When very watery, urine presents a faint greenish tint, as in early infancy, and in hysteria and chlorosis. If bile or blood be present in the urine, a variety of colours, from red to brown, blackish-green, or apple-green are produced, the latter hue being sometimes indicative of *cystine*. A reddish tint may be caused by *purpurine* or by *blood*; if by the former, congestion of the portal circulation, or disease of the liver or spleen, may be inferred; if by the latter, hæmorrhage in some part of the urinary passages has occurred. In the former case the specific gravity is moderate, and heat produces no change; in the latter, heat and nitric acid occasion turbidity, and blood-disks are seen under the microscope. A brownish tint is caused by a concentrated or dense state of the urine, as in fevers, the specific gravity being high; or by obstruction to the discharge of bile in some part of the biliary apparatus, and the presence of some or all the elements of bile in the circulation; or by the existence of blood in a less degree or altered state, and shown by the tests just mentioned. Blood and bile may occasion a greenish-brown tint, the former when the urine is alkaline, the latter when the urine is very acid. A grass-green hue of the urine indicates excess of sulphur and the presence of cystine. It is unchanged by heat or nitric acid. It should not, however, be overlooked that numerous articles of diet and of medicine affect the appearance of the urine. Chima-phyla, hæmatoxylin, indigo, rhubarb, senna, &c., produce this change in a marked degree.

19. *c.* The *fluidity* of the urine sometimes varies. It is more or less viscid, owing to the presence of mucus or pus, or both, especially when alkaline, and in the layer formed at the bottom of the vessel; and in a slight degree in diabetes mellitus, when the frothiness caused by agitation continues for some time. Although fluid while warm, it becomes in rare cases jellatinous on cooling, owing to the presence of self-coagulating albumen or fibrin. This state indicates severe organic disease of the kidneys. I have, however, met with it at advanced stages of pregnancy.

20. II. The *CHEMICAL COMPOSITION OF THE URINE* has engaged the attention of chemists and physiologists for many years; and even now the elements contained in this fluid, although nearly, if not altogether, ascertained, are still topics of controversy, as respects either the origin of certain of them, or the successive changes of which they may be the ultimate products. As to the general principle, that the urine is an excretion by which the blood is depurated from the effete materials carried into the circulation from the metamorphosis and waste of the tissues, &c., as stated above (§ 3-10) and in the commencement of this work (*see* BLOOD, § 115-160), no doubt can now exist; but the successive changes which these elements or materials undergo during their absorption and passage from their origins and sources, during their circulation, and during their ultimate discharge—from their origins to their elimination from the body—have been long topics of research and discussion, especially by the chemical physiologists and pathologists of recent times, who have been more disposed to view them as altogether chemical, than as vital and as modified, and even more or less altered, by the states of vital power and vascular action. To the specialist in medicine the chemical doctrine presents itself in its most favourable

aspect, as placing urinary pathology in an isolated yet scientific position. To the general or legitimate physician, the conditions of the urine, in all their phases, and in the successive changes from their origins to their ultimate results, are viewed as ever-varying effects of the influence of vitality throughout the frame, as manifested by the functions of digestion, assimilation, nutrition, metamorphosis, waste, and depuration; all which are not only under the complete and constant dominion of life, but are also the necessary agencies of the continuance of life; this department of pathology being inseparable, in its philosophic as well as in its practical relations, from all others which comprise the whole range and circle of morbid actions.

21. The *urine in health* contains: 1st, certain *organic products*, namely, urea, uric acid, creatine, creatinine, colouring and odorous elements; these more especially result from the metamorphosis and waste of the tissues and of the blood, and are separated from the latter by the kidneys; also other ingredients, more particularly lactic and hippuric acid, developed during the process of assimilation, and accidental matters carried into the circulation; 2d, *inorganic products*, being saline combinations, derived from the food, especially sulphates, phosphates, chloride of sodium, and soluble salts taken with the ingesta, and often decomposed in their transit into and from the blood; also saline substances, generated chiefly from the processes of destructive metamorphosis and waste, and of depuration, as sulphates and phosphates; 3d, *matters derived from the urinary passages*, being chiefly mucus, debris of epithelium, and a minute quantity of phosphate of lime present in mucus. M. BECQUEREL gives the following as the average composition of urine in males and females, and the quantity discharged in the 24 hours.

	Urine in Men.		Urine of Women.		Mean of Both.	
	In 24 Hours.	In 1000 Grs.	In 24 Hours.	In 1000 Grs.	In 24 Hours.	In 1000 Grs.

Organic matters and volatile saline combinations. }	176·	9·26	145·	8·	160·5	8·6

22. *a.* *Urea*.—This important excretion, composed of C 2, N 2, H 4, O 2 = 60, is the form in which a large quantity of nitrogen is eliminated from the body; 270 grains of urea being discharged by a healthy man in the 24 hours. This substance is the product of the destructive metamorphosis or waste of organized parts (§ 9, 10); but it is so rapidly carried out of the blood by the kidneys as to admit of only minute quantities of it escaping by the skin, unless when the functions of the kidneys are interrupted, and then it is discharged both by the skin and by the intestines in greater quantities. The *food* has a remarkable influence upon the quantity of urea in the urine. Dr. LEHMANN found the quantity of urea excreted by his kidneys while living on

strictly animal food, and while restricted to vegetable diet, as shown by the preceding table.

[*Urea* has been repeatedly detected in the blood under ordinary circumstances, and especially after extirpation of the kidneys in the lower animals; but it is removed with such rapidity by the kidneys, that there is probably never more than a fiftieth of one per cent. of the circulating blood. Though its source is supposed chiefly to be found in the food and the waste of muscular tissue, yet both *creatine* and *inosic acid* produce it in their descending metamorphosis. From the fact that *caffeine* and other substances increase its amount, the seat of its production would seem to be the blood itself. Dr. J. C. DRAPER, of New York (*Inaugural Dissertation*, 1856), from experiments on the urine of persons in different conditions of motion and rest, and by an examination of the diurnal and nocturnal variations in the amount of urea voided, con-

	Animal Food.	Vegetable Food.	Mixed Diet.	Non-nitrogenized Diet.
Urea in the urine } in 24 hours..... }	519·2	346·5	500·5	237·1

pared with an invariable standard, gives reasons for concluding that the differences in the amount of urea excreted are almost entirely attributable to the influence of the food, an individual in such a state of comparative rest as is observed during treatment for a fractured leg not excreting by any means so much less urea as might have been anticipated when compared with another individual who walked thirteen miles at the rate of four and a half miles an hour. But on examining the influence of the food it appears to be well marked. The greatest amount of urea is excreted within a few hours after dinner. Another maximum occurs also just after breakfast; but during the eight night hours far less is excreted than during the same period in the afternoon. The ingestion of food thus exercising so rapid and marked an influence on the quantity of urea, he refers to it as the cause of the increased excretion of that substance during the course of the day rather than to the increased motion of exercise then indulged in; and in view of this conclusion, it becomes probable that the nitrogen of the wasting muscular tissues escapes, not under the form of urea through the kidneys, but through the skin, or perhaps even as free nitrogen from the lungs. (*"Human Physiology,"* by J. W. DRAPER, 8vo, New York, 1856.)

23. According to LECANU, the quantity of urea and of *uric acid* excreted in the 24 hours is very much influenced by age. The following are the results of his experiments, as to the amounts of these substances excreted in the 24 hours:

	Urea.	Uric Acid.
Adult men .....	431.9 grs.	13.09 grs.
Adult women.....	294.2 "	10.01 "
Very old men (34 to 86 years).....	124.8 "	6.77 "
Children (under 8 years).....	133.2 "	3.98 "

[To detect urea, Dr. BIRD recommends to place a drachm of urine in a watch-glass, and add about half that quantity of colourless nitric acid. If a normal proportion of urea exist, no change, except a darkening in tint, and the evolution of a few bubbles, will be observed, unless the weather be very cold, or the glass be placed in a freezing mixture, and then a delicate plumose crystallization of nitrate of urea will commence at the edges of the fluid. Under ordinary circumstances no crystals of urea will appear, unless the urine be concentrated by previous evaporation. In some cases an excess of urea exists, and then a rapid formation of crystals of nitrate of urea occurs, sometimes so copious that the mixture becomes nearly solid. Dr. B. thinks it important, when this is the case, to measure and ascertain the specific gravity of the whole quantity of urine passed by the patient in 24 hours; for unless this equals or exceeds the average proportion of health, there is no proof that an actual excess of urea is excreted by the kidneys. A particular specimen of urine may appear richer in urea than natural, from the diminished amount of water present.]

24. *b. Uric Acid.*—Uric or lithic acid, composed of C 70, N 4, H 4, O 6 = 168, is excreted by the kidneys to the amount of 8.1 grains in the 24 hours. Dr. PROUT's opinion, confirmed by Dr. B. JONES and Dr. G. BIRD, is that the greatest portion of the uric acid always exists in the blood in combination with ammonia; for this acid requires 10,000 parts of water at 60° for solution, while there does not exist quite 2500 times its weight. Urate of ammonia is soluble in 480

times its weight of water; and as it occurs in urinary deposits, it requires for solution 2789 parts of urine, according to the researches of Dr. B. JONES, who has shown that the presence of a moderate quantity of saline matter increases its solubility. Dr. G. BIRD states the following as the mode in which uric acid exists in healthy urine. "Uric acid, at the moment of its separation from the blood, comes in contact with the double phosphate of soda and ammonia, derived from the food, forms urate of ammonia, evolving phosphoric acid, which thus produces the natural acid reaction of urine. If the whole bulk of the urine be to the urate of ammonia formed, not less than about 2701 to 1, the secretion will, at the temperature of the air, remain clear, but if the bulk of fluid be less, an amorphous deposit of the urate will occur. On the other hand, if an excess of uric acid be separated by the kidneys, it will act on the phosphate of soda of the double salt, and hence, on cooling, the urine will deposit a crystalline sediment of acid sand, very probably mixed with amorphous urate of ammonia, the latter usually forming a layer above the crystals, which always sink to the bottom of the vessel." (*Op. cit.*, 84.)

25. Without referring to LIEBIG's views as to the physiological origin of uric acid, which are contradicted by the experiments of LEHMANN, and merely stating that these views are not corroborated by any subsequent researches, I may give the results of the researches of this latter physician:

Diet.	Quantity excreted in 24 hours of		Proportion of Uric Acid to Urea.
	Uric Acid.	Urea.	
Exclusively animal	22.64 grs.	819.2 grs.	1: 36.1 grs.
Mixed animal and vegetable.	18.17 "	505.0 "	1: 27.5 "
Exclusively vegetable	15.7 "	346.5 "	1: 22. "
Food free from nitrogen.....	11.24 "	237.1 "	1: 21. "

Dr. BENICE JONES, who has investigated this and other subjects connected with the chemico-pathology of the urine, with great scientific acumen, has shown the *immediate* influence of food on the quantity of uric acid contained in the urine to be as follows:

	Specific Gravity.	Grains. Uric Acid.
<i>In 1000 Grains of Urine:</i>		
After animal food.....	1027	1.022
Before " ".....	1024	0.049
After vegetable food ..	1025	1.010
Before " " ..	1024	0.049

From these and other researches and considerations, it may be inferred that uric acid is derived from the nitrogenized elements of the effete molecules of the tissues, and from the elements of food abounding in nitrogen, which are not assimilated into the healthy constituents of blood; and probably from the latter source, in larger proportion; and thus these nitrogenized elements are excreted from the blood in the states of uric acid, of uric acid combined with ammonia, and of urea; the causes of the preponderance of either of these being not satisfactorily explained.

26. *c. Lactic acid and lactate of ammonia* were said by BERZELIUS to exist in the urine, but were denied by LIEBIG. That lactic acid exists in the blood, and is excreted by the skin in health, and more largely in some diseases, is admitted. It is,

however, found in the urine of herbivorous animals; and it probably undergoes some change before it is excreted by the kidneys in the human subject. Dr G. BIRD considers that what was mistaken for lactic acid in urine is really a mixture of *creatine* and *creatinine*, these substances being forms in which the nitrogenized elements of worn-out structures, especially muscular tissues, are removed from the system. Dr. PROUT believed that several of the constituents of urine were derived from the destructive metamorphosis of distinct and separate tissues, and these substances appear to support his views.

27. *d. Hippuric, or urobenzoic acid*, exists chiefly in the urine of herbivorous animals, and occasionally in that of man. Its quantity in health is not constant, probably owing to the nature of the food. It is, next to *bile* and *purpurine*, the richest in carbon of any of the products of vital chemistry; and hence its abundance in urine may depend upon the states of biliary secretion and of the respiratory functions, impairment of these increasing its excretion by the kidneys.\*

[Though we are not disposed to deny that chemistry has been of great service in the diagnosis of calculous and urinary disorders generally, yet there is reason to believe that the treatment, to be successful, is not always to be regulated by the chemical indications present. The alkalies, especially the bicarbonate of potash and bicarbonate of soda, when given freely, especially at or near the times of eating, interfere with the process of digestion, by neutralizing the gastric acids, and thus aggravate the difficulty by deranging this important function. These, as well as other alkaline substances, should be given at least two hours from the time of meals, in connexion with the vegetable tonics. Prof. M. PAINE, in his very able work, "*The Inst. of Medicine*" (p. 233), thus speaks of the aid derived from a knowledge of the chemical constitution of the urine: "Coming to the bed-side, we find that all that is practically useful in relation to the urine is generally best ascertained by mere inspection; and upon this subject we have all, and more than is desirable, from HIPPOCRATES himself. Those philosophers, however, who are employed in interrogating disease by chemical analysis, are not often, or long, in the chambers of the sick. They carry on the investigation of morbid processes in the laboratory of the chemist, and then and there fabricate the appropriate reagents. He who studies organic nature according to the method of solidism and vitalism, has neither the leisure for these most difficult, unattainable, and laborious analyses, nor would they have any influence on his judgment as to the pathology or treatment of disease in the midst of such a multitudinous variety as is presented by the vital phenomena of disease. Of one thing, also, we may rest assured, that nature has supplied all those ready means for interpreting disease that may be necessary for immediate action; nor can we often delay the treatment of acute disease

\* To detect *hippuric acid*, evaporate a few ounces of urine to a sirupy consistence, and then add an excess of hydrochloric acid; a mixture of hippuric and uric acids will then be separated and fall to the bottom of the vessel. After a few hours' repose, the supernatant fluid should be decanted, and the deposit washed in a very little cold water. On boiling the residue in alcohol, in which uric acid is insoluble, the hippuric acid will be dissolved, and by spontaneous evaporation is left in thin, delicate needles, strongly coloured from adhering impurities.]

for consultation with the laboratory. In respect to the blood, were it even practicable to learn from analysis its variable conditions in disease, it would reflect no light upon morbid states of the organs, since the qualities of that fluid vary with every varying change in the vital conditions of the solids, and therefore, too, would fail to indicate in the least the appropriate remedies. This is also true, in a general sense, of the urine and all other excretions and secretions. The ready sight, their sensible properties, the vital phenomena, physical signs, experience, and general principles, must be our guide. These may sometimes be facilitated by extraordinary modes of observation, but which are always within the reach and clear understanding of every practitioner, such as the usual mode of examining the blood in inflammatory diseases, evaporating the urine in diabetes, &c. On the contrary, were the humoral doctrines correct, the teaching and the practice of medicine should be restricted to chemists alone, since there is no branch of inquiry so difficult as organic analyses, while their uncertainty would soon prove that the *vis medicatrix naturæ* is the only ordination of nature for the maladies of the urine race."]

28. *c. Butyric acid* is sometimes found in the urine, and may be either referred to the butter used in food, or to the imperfect assimilation of saccharine matter. It is seen also in the creamy deposit formed in diabetic urine. This acid may also be derived from protein compounds.

29. *f. The colouring matter of urine* has been differently accounted for by SIMON, PROUT, HELLER, G. BIRD, and SCHERER. The last-named physician attributed it to the destructive metamorphosis or waste of red-blood corpuscles. Dr. G. BIRD investigated its nature and composition, gave it the name of *purpurine*, and viewed it as a principle of urine chiefly in disease, and as a result of impaired excretion of carbon by the lungs and liver, this element being, when existing in excess in the blood, partly eliminated by the kidneys in this form (§ 27, 28).

30. *g. Sulphur extractive* exists in urine, and is derived from the metamorphic destruction of albuminous and fibrinous tissues, which contain sulphur and traces of phosphorus. "While the greater quantities of their protein elements are converted into creatine and its allies and urea, a small proportion containing the sulphur and phosphorus is eliminated by the kidneys in the form of this peculiar extractive matter." The taurine, a constituent of bile, may also be one of the sources of the sulphur extractive of the urine. The nature of the food may also contribute materially to the quantity of this constituent

31. *h. Ammonia* exists in urine "combined with uric acid, and probably with phosphoric acid and soda, forming the triple compound known as microcosmic salt."

32. *i. The fixed salts of urine* are those which are left after the other ingredients are destroyed by a red heat. They amount to nearly 140 grains in the 24 hours, and consist of combinations of chlorine, sulphuric and phosphoric acids, with soda, lime, magnesia, and potass. Of these the combinations of chlorine and phosphoric acid are probably derived from the food. Dr. G. BIRD considers that the phosphoric acid and soda in the urine exist in the state of the common rhombic phosphate unless it be combined with the phosphate of ammonia. The soluble phosphates

far exceed in quantity the insoluble salts, and are derived directly from the food, as well as from the albumen and other elements of the blood. The insoluble phosphates, forming part of the structure of the body, and derived from the blood during the process of nutrition, are conveyed back to the blood during the metamorphosis and waste of the structures, and are eliminated by the kidneys. "Some portion of the phosphoric acid of the urine is in all probability generated from the action of oxygen on many of the structures of the body, into the composition of which phosphorus largely enters, as the brain and nervous system generally. But the greatest part of the phosphoric acid is derived ready formed from without; the phosphates of lime and magnesia abounding in milk and most varieties of vegetable food; while the basic alkaline phosphates exist in flesh, in wheaten flour, leguminous seeds, as beans, peas, &c." The interesting researches of Dr B. JONES have shown that the quantity of phosphates, in a given quantity of urine, bears some relation to the periods of taking food, and to the nature and composition of the food. He found the quantity of phosphatic salts to be much greater after a diet restricted to vegetable, than to animal food. The quantity of phosphates of lime and magnesia in the urine is considerably increased after the ingestion of soluble salts of these two earths. The alkaline phosphates are most abundant shortly after a meal composed chiefly of bread, and are not materially affected by the circumstances which influence the excretion of the earthy salts. "A part only of the earthy phosphates contained in the food is absorbed into the circulation, the greatest proportion escaping by the intestines." BERZELIUS found in three ounces of human fæces six grains of earthy phosphates. The insolubility of the salts in water accounts for their presence in the fæces. A small quantity of phosphorus also exists in the urine in a non-oxidized form. The excess of phosphoric acid often found arises from the oxidation of the phosphorus of the urine.

33. *k.* The quantity of *sulphuric acid* in the urine is too great to be accounted for by its presence in the food as saline combinations; and sulphuric acid has been found in the urine while food quite free from sulphates has alone been taken. According to G. BIRD and MULDER, the origin of this acid is to be referred to the oxidation of the sulphur which exists with phosphorus in those tissues which contain albumen and fibrin. During the metamorphosis or waste of tissues, oxidation of the sulphur occurs, and explains the presence of at least a portion of the sulphuric acid met with in the urine. The existence of more than twenty per cent. of sulphur in taurine—one of the products of the metamorphosis of bile—accounts for a portion of the sulphuric acid, by referring it to the oxidation of the biliary sulphur during the recrementitious offices of bile in the economy. As a portion of sulphur is excreted from the body in a non-oxidized form, a part only of the sulphur not required for the purposes of the animal economy undergoes oxidation. Professor RONALDS found, in five specimens of urine of healthy persons, the proportions of sulphuric acid, and of the non-oxidized sulphur, existing in 1000 grains, to be as follows: 1.06; 0.17—1.46; 0.18—1.42; 0.18—2.44; 0.153—1.32, 0.165.

34. Dr. BENCE JONES has shown, by his interesting researches connected with the subject, that

the salts of this acid are increased in the urine by any kind of vegetable or animal food; that exercise does not appear to increase them, nor the administration of sulphuric acid, unless in large quantities; and that the ingestion of sulphur, or of the sulphates of soda or magnesia, always greatly augments the quantity of the sulphuric salts in the urine.

35. *l.* The *chloride of sodium* of the urine is obviously derived from the common salt taken with the food. Some of the saline constituents of the urine may be readily recognised by the crystalline forms they present when the urine is evaporated on a glass plate. MM. REGNAULT, REISER, and BURRAL have shown that the chloride of sodium increased the excretion of nitrogen, as evinced by the augmentation of urea and the nitrogenized compounds in the urine. It may be inferred that common salt produces salutary effects: 1st, by furnishing hydrochloric acid to the stomach; 2d, by furnishing soda to the bile; 3d, by aiding the metamorphoses of the blood globules and of the tissues; and, 4th, by promoting the depuration of the blood. The absence or diminution of chloride of sodium in the urine of patients labouring under pneumonia, noticed by REDTENBACHER, was attributed to the alteration of diet during this disease. But Dr. LIONEL BEALE has established the following propositions, which show the insufficiency of this explanation: 1st. Chloride of sodium is totally absent from the urine of pneumonic patients at the period of complete hepatization of the lung. 2d. The chloride reappears after the resolution of the inflammation. 3d. The chloride exists in the blood in the largest quantity when most abundant in the urine, and *vice versa*. 4th. The chloride exists in very large quantity in the sputa of pneumonic patients. 5th. There is reason to believe that the chloride in pneumonia is determined toward the inflamed lung, and is reabsorbed and removed on the resolution of the inflammation. (*Transactions of Medical and Chirurgical Society*, vol. xxxv., p. 374, &c.) I may, however, remark that the quantity of chloride in the expectoration is increased beyond that existing in healthy pulmonary mucus, and is diminished in the urine, in acute bronchitis, in pleurisy, and in phthisis, although not so remarkably as in pneumonia.

36. III. THE FORMATION OF URINARY DEPOSITS.\* *Et seq.*—When the several constituents

\* CLINICAL EXAMINATION OF THE URINE.—Dr. COLDING BIRD has given the following recommendations for ascertaining the state of the urine in disease, provided that it be an average specimen of that passed in the preceding twenty-four hours, or that resulting from the first micturition after a night's rest, unless the urine secreted at other times be required.

*A. Urine without Deposit, or poured from the Sediment.*—After ascertaining the acid, alkaline, or neutral states of the urine by means of test-papers, a little of the urine should be heated in a metallic spoon over a lighted candle, or in a test-tube over a spirit-lamp; and if a deposit occurs, albumen or an excess of the earthy phosphates is present; the former if a drop of nitric acid does not redissolve the deposit, the latter if it does. "If the urine be very highly coloured, and be not rendered opaque by boiling, the colouring matters of bile or purpurine are present. To determine this, pour a thin layer of urine on the back of a white plate, and allow a few drops of nitric acid to fall in the centre; an immediate and rapid play of colours, from bluish-green to red, will be observed, if bile; but no such change will be observed if purpurine alone exists. Should the high-coloured urine alter in colour or transparency by heat, the presence of blood should be suspected. If the addition of nitric acid to deep-red urine, unaffected by heat, produces a brown deposit, an excess of uric acid exists. If a specimen of urine be pale, immerse the gravimeter, and if the spe-

of the urine are in due relation to each other, the urine is clear, and of a pale amber colour. Its transparency is but slightly affected on cooling by the gradual subsidence of a slight mucous cloud sometimes entangling a few microscopic crystals of uric acid; but when one or more of these constituents "exist in real or comparative excess, or a new substance is superadded, the urine does not generally remain clear, but either immediately

specific gravity be below 1012, there is a considerable excess of water; but if above 1025, the presence of sugar, or a superabundance of urea, is indicated. To determine the existence of either of these conditions, place a few drops of the urine in a watch-glass, add an equal quantity of nitric acid, and allow the glass to float in some cold water; crystals of nitrate of urea will appear in two or three minutes if the latter exists in excess. Should this change not occur, the urine must be examined specially for sugar, which, it must be remembered, may exist in small quantities, without raising the specific gravity of the fluid." For this purpose, boil a small portion with an equal bulk of liquor potassæ, in a test-tube, and the development of a brown colour will show the almost certain existence of sugar. An excess of colouring matter, rich in carbon, should always be sought after on account of its pathological importance. "This is readily done by boiling some urine in a tube, and, while hot, adding a few drops of hydrochloric acid. If an average proportion of the pigment exist, a faint red or lilac colour will be produced; but if an excess is present, it will be indicated by the dark-red, or even purple tint assumed by the mixture. Should the urine be alkaline, add a drop of nitric acid; if a white deposit occurs, albumen is present; if brisk effervescence follows the addition of the acid, the urea has been converted into carbonate of ammonia" (p. 16, 17).

*B. Examination of the Sediment deposited.*—"If the deposit is flocculent, easily diffused on agitation, and scanty, not disappearing on the addition of nitric acid, it is chiefly made up of healthy mucus, epithelial debris, or occasionally, in women, of secretions from the vagina, leucorrhœal discharge, &c. If the deposit is ropy, and apparently viscid, add a drop of nitric acid; if it wholly or partly dissolves, it is composed of phosphates; if but slightly affected, of mucus. If the deposit falls like a creamy layer to the bottom of the vessel, the supernatant urine being coagulable by heat, it consists of pus. Urine sometimes appears opaque from the presence of a light flocculent matter diffused through it, presenting neither the tenacity of mucus nor the dense opacity of pus. Although scarcely sufficient in quantity to interfere with the perfect fluidity of the urine, if a little be placed in a test-tube, and agitated with an equal bulk of liquor potassæ, the mixture will often become a stiff, transparent jelly. This peculiar appearance is demonstrative of the presence of the exudation, or large organic globules formed under the influence of irritation, providing the urine does not coagulate by heat; for should it do so, the existence of minute quantities of pus may be suspected."

"If the deposit is white, it may consist of urate of ammonia, phosphates, or cystine; the first disappears on heating the urine, the second on the addition of a drop of diluted nitric acid, while the third dissolves in ammonia, and the urine generally evolves an aromatic odour like the sweet-briar, less frequently being fetid. If the deposit be coloured, it may consist of red particles of blood, uric acid, or urate of ammonia stained with purpura. If the first, the urine becomes opaque by heat; if the second, the deposit is in visible crystals; if the third, the deposit is amorphous, and dissolves on heating the fluid. Oxalate, and, more rarely, oxalurate (?) of lime, are often present, diffused through the urine, without forming a visible deposit; if this be suspected, a drop of the urine, examined microscopically, will detect the character of the crystals. If the urine be opaque, like milk, allowing by repose a cream-like layer to form on the surface, an emulsion of fat with albumen is probably present. Agitate some of the urine, with half its bulk of ether, in a test-tube, and, after resting a few minutes, a yellow ethereal solution of fat will float on the surface of the urine, a tremulous coagulum of albumen generally forming beneath it."

Dr. G. BIRD adds, that much of the little time required for the investigation thus sketched may be saved by remembering the following facts:—"If the deposit be white, and the urine acid, it, in the great majority of cases, consists of urate of ammonia; but should it not disappear by heat, it is phosphatic. If a deposit be of any colour inclining to yellow, drab, pink, or red, it is almost sure to be urate of ammonia, unless visibly crystalline, in which case it consists of uric acid" (p. 18-21).

ly upon being voided, or at least on cooling, becomes more or less turbid." When the urine, on cooling, becomes covered with a thin membrane-like scum, a *pellicle* is said to exist. When the substance causing opacity floats between the surface and the lower portions of the fluid, it is said to form a *cloud*. And when this falls toward the bottom of the containing vessel, the appearance was termed *encorema*. When a positive deposit collects at the bottom of the vessel, the term *sediment*, the hypostasis of the ancients, is commonly applied. The terms *pellicle*, *cloud*, and *deposit*, or *sediment*, are those commonly used in describing the states of the urine. These appearances are generally not fully developed until the urine is cooled down to the temperature of the air. This is especially the case with those deposits which are soluble in warm water; as the urates, particularly the urate of ammonia, which constitutes the chief part of reddish and fawn-coloured amorphous sediments.

37. *Urinary deposits*, including all substances which disturb the transparency of urine by their presence, whether they subside to the bottom of the vessel or not, have been divided by Dr. G. BIRD into: 1st. "Deposits composed essentially of ingredients derived, directly or indirectly, from the metamorphoses of tissues—(to which I would add, from the metamorphosis and waste also of the red globules, fibrin, and other constituents of the blood)—or from the organic elements of food; namely, uric acid and urates, uric oxide, oxalate of lime, oxalurate of lime, and cystine. 2d. Deposits composed of ingredients for the most part of inorganic origin, including phosphate of lime, ammonio-phosphate of magnesia, carbonate of lime, silicic acid. 3d. Highly-coloured deposits (black or blue) of doubtful origin; viz., cyanourine, melanourine, indigo, Prussian blue. 4th. Deposits consisting of non-crystalline organic products, including—*organized*: blood, pus, mucus, organic globules, epithelium, spermatozoa, confervoid bodies, vibronces; *non-organized*. milk, fatty matter, stearolith."

38. *i. DEPOSITS OF URIC ACID AND OF ITS COMBINATIONS.*—Uric acid, uncombined with a base, forming a deposit, is invariably in crystalline forms. But the crystals are seldom so large as to admit of their figures being recognised without the aid of the microscope. Uric acid presents a yellow or amber colour, unless when mixed with urate of ammonia, which is frequently the case, and then it is of a much paler hue. These deposits present every shade of colour, from the palest fawn to the deepest amber or orange-red. The deeper the colour of the urine the darker are the deposits

39. *A. Diagnosis of Uric Acid Deposits*—When heated in the urine, the uric acid deposit is not dissolved; the crystals merely become opaque. When mixed with urate of ammonia, Dr. G. BIRD recommends the urine to be warmed in a watch-glass; the acid then becomes visible at the bottom of the glass as soon as the urate dissolves. Heated with liquor potassæ, the uric acid deposit dissolves, forming urate of potash of ready solubility in the alkaline fluid. "Hydrochloric and acetic acids are without any action; but nitric acid readily dissolves it, and by careful evaporation a residue of a beautiful pink colour, becoming of a rich purple on being held over the vapour of ammonia, is left. This coloured residue is the murexid of LIEBIG, the purpurate of ammonia of

**PROUT.** Exposed to heat in a platinum spoon, the uric acid deposits readily burn, evolving an odour of bitter almonds, and finally leave a small quantity of a white ash, which contains phosphate of soda, or lime, or both."

40. *When urine contains an excess of uric acid* it generally forms crystals on cooling, uric acid being seldom deposited before emission. Sometimes, especially in the urine of gouty persons, many hours elapse before any is deposited, although a large quantity is present. Occasionally the acid is not deposited, but remains on the surface as a crystalline pellicle, presenting an iridescent play of colours in a bright light. Urine of a deeper amber colour than natural, or of a reddish-brown colour, usually deposits the largest amount of this acid; but very high-coloured urine seldom deposits uric acid until after the addition of a stronger acid; and urine does not deposit all its uric acid until decomposition has commenced. Urine depositing this acid always reddens litmus paper, and often contains an excess of urea, so as to crystallize when mixed with nitric acid. Its specific gravity is generally above 1.020, excepting in infants, in whom deposits of uric acid are common, although the urine may be pale and of a much lower density. These deposits "appear as a yellow crystalline sand, while the supernatant urine is of low specific gravity, often 1.006, as pale as water, and contains very little urea." This circumstance admits of explanation from the small proportion of alkaline phosphates, the presumed solvent for uric acid in the urine of infants. For the various microscopic characters of uric acid deposits, which can only be satisfactorily shown by engravings, I must refer the reader to Dr. G. BIRD's interesting work.

[*Microscopic Characters.*—All the varieties of uric acid crystals may be traced to some modification of the *rhombic prism*, the normal crystalline form of this substance. The rhomboidal crystals are sometimes so thin as to be merely pale, lozenge-shaped laminae; more generally, however, they are thicker. Many of them appear nucleated, as if one crystal included another. It seldom happens that the angles of these are sharply defined, the two obtuse angles being most generally rounded off, and sometimes the acute angles are blunted, so that the whole crystal appears elliptical. Where the deposit has been of long continuance, the rhomboid outline of the crystal is replaced by a square one. Several accidental varieties of these rhomboid and square crystals exist, the most curious of which presents a spindle-like figure, the obtuse edges being rounded, and the margin on either side excavated; and some appear to be composed of flattened cylinders. Some are very thin, longer than broad, representing square tables, with smooth or serrated sides and edges. Another variety forms thick, rhomboidal, cohering prisms, and another still, aggregated lozenges in spinous masses. When the urine cools very suddenly, or a strong acid is added to it, uric acid is sometimes precipitated in irregular masses resembling irregular fragments of yellow quartz. We have observed this appearance this very day (June 28, 1857) in the urine of a patient labouring under renal calculus of the uric acid kind.]

41. *B. Diagnosis of Deposits of Urate of Ammonia.*—These vary in colour, from white, through every tint, to a pale fawn (the oftenest met with), brick-red, pink, or purple. All these deposits

have certain characters in common. They never take place until the urine has cooled, and quickly disappear on the application of heat. The darker coloured deposits require a higher temperature for solution than the paler; and when the urine is scanty and concentrated, as in acute rheumatism, the addition of a little water may be required before they quite disappear. The addition of liquor ammoniæ or liquor potassæ quickly dissolves deposits of urate of ammonia, rendering the urine a little turbid from the precipitate of earthy phosphates. Deposits of urate of ammonia always contain small quantities of the urates of lime and soda, and often of magnesia and potass.

42. *Urine depositing urate of ammonia* presents several modifications: 1st, a pale urine of low specific gravity (1.012) with a nearly white deposit, which, instead of entirely falling, forms masses in the fluid, and appears as a mucous pus. The application of heat shows at once its real nature by causing its disappearance. 2d. A pale amber-coloured urine, of a specific gravity about 1.018, which, on cooling, deposits a copious fawn-coloured substance resembling powdered bath-brick mixed in the water, but very readily disappearing on applying a gentle heat. This deposit occurs often, readily disappears, and frequently attends a cold, obstructed perspiration, or slight indigestion. 3d. A deeper coloured urine, of a higher specific gravity (from 1.022 to 1.026), and deposits, on cooling, a reddish-brown sediment—the well-known brick-dust or lateritious sediment. This variety generally is present during febrile excitement, and becomes turbid on the addition of a drop of nitric acid, "not from the coagulation of the albumen, but from the precipitation of uric acid in very minute microscopic rhomboidal crystals." 4th. Urine of a very deep colour, approaching to a copper or purplish tint, or to purplish hue. This colour Dr. G. BIRD attributes to the presence of *purpurine*. He adds that, whenever a deposit of urate of ammonia occurs in such urine, either spontaneously or by immersing it in a freezing mixture, it combines with the pink pigment, forming a kind of lake, and which is often so abundant as not to entirely disappear by heat, until the urine is diluted with water. This state of the urine is often observed in acute rheumatism, gout, in diseases of the liver, spleen, &c., and has been attributed to the obstructed elimination of carbon.

[*Microscopic Characters.*—Dr. BIRD states that when a drop of urine, turbid from the presence of urate of ammonia, is placed between two pieces of glass and examined with the microscope, a mere amorphous precipitate is first seen; but, on minute examination, this is seen to be composed of myriads of excessively minute globules adhering together, forming little linear masses, often mixed with crystals of uric acid. Sometimes, especially if the urine has been long kept, the minute particles cohere, and form small opaque spherical bodies, appearing black by transmitted light, on account of their opacity. When examined by reflected light, on a black ground, they present a buff or fawn colour. On the application of slight heat to the drop of urine, the particles of urate of ammonia disappear, again becoming visible on cooling. A good mode is to place a drop of the turbid urine in a watch-glass and gently warm it. As soon as it has become clear, add a drop of almost any acid (the hydro-

chloric is perhaps the best); the muddiness previously produced by the urate will, on examination, be found to be replaced by lozenges of uric acid of a rhomboidal form. Very rarely the urate of ammonia occurs in large globules mixed with crystals of uric acid. This is occasionally observed in albuminous urine, and by its opacity is best observed by reflected light.]

43. ii. PATHOLOGICAL RELATIONS OF URIC ACID AND URATE OF AMMONIA.—Independently of changes in the quantities of these substances in the urine, caused by the quantity and nature of the food, very important alterations of the proportions of these substances accompany and characterize various pathological conditions of the frame. Uric acid and its combinations have been attributed to two sources, viz., the waste or disintegration of the tissues, and nitrogenized food. But it appears to me that too large a share of these sources has been imputed to the former (which is more correctly the nutritive metamorphosis, and waste of the tissues), while the metamorphosis and waste of the globules, fibrin, and albumen of the blood, as contributing to the formation of these substances in the urine, have been overlooked. In disease, especially in acute diseases, as long as the kidneys are enabled to discharge their functions, an increase of uric acid and its compounds appears in the urine; and this increase is to be imputed chiefly to the waste of the tissues and of the hæmato-globuline, for little or no nitrogenized food is generally taken in these cases, but emaciation, and with this more or less of anæmia supervene. The anæmia, which is often remarkable, especially in the advanced progress of these diseases, is often overlooked in acute rheumatism, gout, fevers, diseases of the liver, spleen, &c., the elements and sources of uric acid and its compounds are abundantly supplied by the states of the blood to the kidneys, and uric acid, both pure and combined, is greatly in excess in the urine. MM. BECQUEREL and L'HERETIER found, in eleven cases of inflammatory fever and twelve of continued fever, the uric acid more than double that in health.

	Acute Inflammations.	Fever	Health.
Specific gravity of the urine .....	1·0216	1·0229	1·017
Uric acid in the urine.	1·041	1·312	0·371

44. That uric acid and its combinations may be formed to some extent in the blood, at least in some diseases, especially gout, rheumatism, erysipelas, &c., and eliminated by the kidneys, is rendered probable by the circumstance of urate of soda having been detected in the blood by Dr GARROD. But the presence of this combination in the blood does not preclude the elaboration of a portion of the uric acid and its compounds, or the modification and metamorphosis of one or more of them, or their elements, by the kidneys.

45. In diseases of debility, especially in those characterized by depressed or exhausted organic nervous power, and by a poor or anæmic state of the circulation in hysteria, chlorosis, disorders of irritation, &c., uric acid and its compounds are greatly reduced in the urine, unless the quantity of urine passed be remarkably diminished, and no deposits are formed.

46. The state of the perspiratory function is too often overlooked by those who attend especially to the urine. Whenever the functions of the skin are impeded or interrupted, those of the

kidneys are augmented; and the results are reversed when the perspiratory actions are increased. But the increase or diminution of either does not consist merely in the watery element, but also in the nitrogenized and other materials held in solution. This reciprocative or vicarious function, and more especially the frequent want or imperfection of compensation existing between these functions, are most intimately connected with the origin of many diseases, and are not the less productive of most dangerous results in the progress of others. I have always insisted, in my lectures (delivered from 1826 until 1842), upon the influence of an insufficiently depurated blood—of effete materials circulating in the blood—owing to impaired function of either the kidneys, the skin, or the intestinal mucous surface and follicles, or of two or all of these; or to an imperfect compensation of function of the others, when one is impaired or interrupted, in causing diseases not only of a serious and acute character, but also of a chronic and obstinate, although not dangerous kind. Most of the diseases of the skin, especially those which are most disposed to become chronic, are induced, or perpetuated, or both, not only by impaired depurating function of the skin and its follicles, but more especially and remarkably also by imperfect action of the kidneys, and of the intestinal mucous surface and follicles; the effete and nitrogenized elements and materials, and their combinations, retained and accumulating in the blood, irritating the cutaneous capillaries, and the capillaries of predisposed and sensitive surfaces and tissues. The crises of fevers and inflammatory diseases are merely the returning functions of depurating organs, and the free discharge by these emunctories of effete nitrogenous elements and materials and their compounds, chiefly by the kidneys, bowels, and skin. This doctrine has been fully elucidated in the *articles* BLOOD, CRISES, and DISEASE (published in 1832 and 1833), and has been applied to the illustration of the causes and phenomena of CRISES (see § 15–20). Long after the publication of my views, Professor LIEBIG referred the products of elimination from the blood by the emunctories, and especially those discharged by the kidneys, to chemical changes, but his explanations are opposed to clinical observation, while the researches of M. BECQUEREL (*Séméiotique des Urines*, &c., 8vo, Paris, 1841) tend to confirm the opinion contained in the articles now referred to.

47. (a) Excess of uric acid, or of its combinations with bases in the urine, the quantity of this fluid being natural, occurs in fevers, acute rheumatism, gout, erysipelas, inflammatory diseases, hepatic and cutaneous complaints, &c., chiefly from the waste and absorption of the tissues, and the metamorphosis of the elements and materials derived from these sources, and from the blood aided by oxygen conveyed into the circulation by the red globules. (b) A similar excess may also arise from an excessive indulgence in animal food, especially in highly nitrogenized flesh-meats, or from an indulgence in this kind of food beyond what is required for the nutrition of the several structures, or from a more moderate use of this food, due exercise, especially in the open air, being neglected. (c) Excess of these substances may occur in the urine, although the supply of nitrogenized food is very moderate, owing to impaired digestive, assimilative, and nutritive func-

tion. (d) Excess may also occur in consequence of impaired or arrested action of the skin and bowels; the kidneys discharging a more or less compensating function, and eliminating a portion or the whole of those elements and their combinations usually discharged by these other emunctories.

48. *Calculus Deposits of Uric Acid and the Urates*.—An abundance of uric acid and of the urates in the urine may occur without producing much disturbance to the urinary or other functions. This is especially the case with urate of ammonia, which can hardly be ascribed to disorder, but rather to the healthy discharge of the depurating function of the kidneys. But, as Dr. G. BIRD has justly remarked, "Uric acid or urates may be deposited in an insoluble form in the kidneys or bladder, and, aggregating, form a mass, on which, by a kind of imperfect crystallization, great quantities of the acid or its salts may be deposited, giving rise to the formation of a calculus. Uric acid is of more serious importance than most other elements of calculous formations, not only from its constituting a large proportion of all urinary calculi, but even when they are chiefly composed of other ingredients, the nuclei on which they are deposited are, in the great majority of cases, composed of uric acid. Of 374 calculi contained in the Museum of Guy's Hospital, at the time I examined them, the nuclei are in 269 composed of uric acid or urate of ammonia. On account of its solubility, urate of ammonia is not a frequent component of entire calculi, although it often enters with other ingredients into their composition. Indeed, calculi wholly composed of this compound are almost peculiar to childhood; in Guy's Museum there are but eight concretions entirely consisting of this substance, although it constitutes the nucleus in eighteen." It is hence very probable that if ever by medical treatment we can succeed in overcoming a calculous diathesis, or dissolving a stone in the act of growth, it will be by means directed to the solution of the uric acid or its combinations" (*Op cit*, p. 154)

[The symptoms attending the crystalline lithic acid deposit are sometimes severe, and chiefly met with among those who use considerable animal food and take but little exercise. The tendency to such deposits is often marked by sharp lancinating pains in the extremities, and by lumbar pains, combined with more or less irritation during micturition; and these symptoms are generally absent if the deposits are of a lateritious character, unless they occur in rheumatism, fever, or gout, when they may be expected to be present. Such crystalline deposits are to be suspected, when transient but sharp pains are experienced by the patient, and a sensation of scalding or irritation is felt after or during micturition, and no other symptom of constitutional disturbance is observed. The patient may labour under more or less derangement of the digestive organs, but not so strongly marked as in the phosphatic and oxalic forms of deposit, which are usually characterized by severe dyspeptic symptoms and constitutional disturbance.]

49 iii TREATMENT OF DEPOSITS OF URIC ACID AND URATES.—From the foregoing, it is apparent that excess of these materials in the urine, and the deposit of them, either in some part of the urinary apparatus, or after the urine is discharged, are contingent upon a variety of ante-

cedent disorders or pathological conditions, which, in individual cases, require due recognition and appropriate means; and not upon those alone, but also, in different cases, or in different circumstances, upon an excessive or improper diet and regimen, or upon insufficient exercise. One of the most important and most generally prevalent of these conditions, more especially when these materials are deposited in large or unusual quantities, and still more particularly when they are deposited in any of the urinary organs, is depressed or exhausted organic nervous power, occasioning impaired digestion, assimilation, and nutrition. This condition suggests the employment of such means as experience has shown to be most efficacious in restoring the organic nervous power to its former energy, throughout the organs devoted to digestion, assimilation, and nutrition. This indication of cure should be fulfilled, 1st, by medicinal treatment; 2d, by suitable diet and regimen; and, 3d, by exercise in the open air, and residence in a healthy locality.

50. a. *Medicinal treatment* comprises the several means of cure already recommended under the separate heads of INDIGESTION, GOUT, PYRO-SIS, &c.; but there are substances to which special reference may be made for removing and dissolving the deposits above noticed, and for counteracting the disposition to their formation. The medicines which may be employed in these cases are either restoratives and tonics, or are solvents of uric acid; and others may be so combined as to operate in this double capacity. The first of these consist chiefly of the tonic vegetable infusions and decoctions; the second of alkalies and alkaline salts; the former being generally made the vehicles for the exhibition of the latter—more especially of the following, viz., the liquor potassæ, BRANDISH's alkaline solution, the carbonates of potass and soda; the citrates, acetates, and tartrates of potass and soda; magnesia, and the citrate and carbonate of magnesia; the biphosphates of potash and of soda; the phosphates of soda and of ammonia, and the benzoic and citric acids. Certain mineral substances are likewise of use, especially the alkaline preparations of iron, the nitrate and oxide of silver or bismuth, and the sulphate and oxide of zinc, which may be given in various states of combination, and in the form of pill. It may be remarked respecting certain of the foregoing, that the preparations, especially the carbonate of the fixed alkalies and the liquor potassæ, are often most beneficially conjoined with the iodide of potassium, and prescribed in a tonic bitter mixture; that the phosphate of soda may be taken freely in gruel, so as to act gently on the bowels; that magnesia will be most beneficial when given with sulphur, and so as to act upon the bowels, kidneys, and skin, which it will generally do when taken at night; and that the biphosphates may be prescribed in stomache infusions with salts of the vegetable acids. Benzoic acid was recommended by Mr. A. URE, to prevent the formation of uric acid. It may be given in doses of five to ten grains, thrice a day, with carbonate or phosphate of soda, or with the carbonate of ammonia, dissolved in boiling water. Citric acid was strongly recommended by Dr. OWEN REES for diseases, especially gout and rheumatism, in which uric acid and urates are abundantly formed; and whether it be given as an addition to the patient's drink, or in combination with the alkalies, it is often of great service. With

magnesia, either in the form of citrate, or as recent lemon-juice or lemonade taken immediately after the magnesia, it is equally beneficial.

51. Most of the diseases, or slight states of disorder in which uric acid and the urates are deposited, are characterized by deficiency of the cutaneous excretion, and insufficient attention is directed to this function in many cases. The restoration of this excretion by means of the warm bath, or the vapour bath, followed by frictions of the surface, by walking, or other active exercises in the open air, is a most important indication of cure where these deposits appear in the urine, both in preventing and in permanently removing the complaints in which they are the general concomitants.

52. *b. The mineral waters* which contain the alkalies, or sulphur, as those of Vichy, of Ems, or of Harrowgate, will also be resorted to with benefit. But whatever be the treatment, the quantity of the flesh-meats used as food should be abridged, and farinaceous and vegetable substances, or the white kinds of fish, boiled, be partly substituted, more especially when active exercise in the open air is not enjoyed, and when the functions of the skin are imperfectly performed.

[We have generally been in the habit of recommending the free use of the *Saratoga* (*Congross-water*), fresh from the spring, if possible, in uric acid gravel, and have rarely failed to find it beneficial. It should be used as freely as possible, short of exciting purgation, and taken at different times in the course of the day. The *Sharon* and *Avon* sulphur waters, as well as those of *Virginia*, have also considerable reputation in the treatment of these cases; and they would be far more beneficial were proper attention paid to the diet.]

53. *c. Uric Oxide—Xanthic Oxide—Xanthine, Pathological Relations of.*—This substance is a very rare ingredient of calculous deposits or concretions, and it has been observed only in single instances by MARCET, LANGIER, LANGENBECK, DULK, BERZELIUS, and MORIN. The chemical constitution and the diagnosis of uric oxide are given by Dr. G. BIRD, to whose work I may refer the reader. The character of urine depositing this substance is not known. The microscopic examination of a fragment of calculus consisting of uric oxide did not furnish any information as respects a crystalline arrangement. The only recorded cases of the formation of this deposit occurred in children, and the calculi formed by it did not exceed a few grains in weight.

54. *iv. PURPURINE, ITS PATHOLOGICAL RELATIONS.*—Deposits of urate of ammonia coloured by this substance (§ 39-42) present tints varying from pale flesh-colour to the deepest carmine. "The presence of purpurine interferes with the ready solubility of the deposit with which it is combined on the application of heat, and free dilution with water is often required to aid its solution." Dr. G. BIRD states that he has never seen purpurine colouring any other deposits except those of urate of ammonia, and hippuric acid when precipitated from concentrated urine by hydrochloric acid. Uric acid scarcely appears to have any affinity for it. It cannot be mistaken for blood, on microscopic examination, owing to the absence of blood-disks. The chemical composition of purpurine occurring in disease is not exactly known. SCHERER states that that generated by the action of hydrochloric acid on urine

consists of 62.51 of carbon, 5.79 of hydrogen, and 31.70 of nitrogen and oxygen. Urinary calculi sometimes present layers of urate of ammonia stained with purpurine. Dr. G. BIRD remarks that all the deposits with which it is combined were, as far as he had observed, amorphous.

55. *A. The Characters of the Urine containing Purpurine.*—When an excess of urate of ammonia is present, it falls to the bottom of the vessel as the urine cools, carrying with it a great part of the purpurine. "If this excess be not present, the urine simply presents a pink or purple colour, and on dissolving white and pure urate of ammonia in it by heat, it is precipitated on cooling, deeply coloured by the purpurine. The presence of the yellow extractive which yields purpurine can be readily discovered by the action of hydrochloric acid. On evaporating urine containing purpurine to the consistence of an extract, and digesting it in alcohol, a fine purple tincture is obtained—the intensity of the tint being rather heightened by acids and diminished by alkalies." The specific gravity of this high-coloured urine, when the colour is as deep as that of brandy, varies from 1.022 to 1.030.

56. *B. The pathological indications of an excess of purpurine* are important. Dr. G. BIRD remarks that the existence of purpurine in urine appears to be "invariably dependent upon some imperfection in the excretion of carbon by these organs, whose special function it is to eliminate this element from the blood, as the liver and lungs, but especially the former. It is hence almost always connected with some functional or structural mischief of the liver or spleen, or some other organ connected with the portal circulation." I have for many years ascribed the presence of this colouring substance in the urine to an increased waste of the red globules of the blood, or of the hæmato-globulin by the kidneys, and that the diseases in which it most remarkably occurs, as fevers, gout, acute rheumatisms, phthisis, &c., are characterized not only by a rapid waste of the tissues, but also of the globules of the blood, giving rise in most cases to marked anæmia. There can be no doubt of biliary disorder, torpor, &c., of the liver—enlargements of the spleen, &c., being often associated with these and other diseases in which purpurine exists in the urine; but in these the waste of the blood-globules is not the less remarkable, this substance disappearing from the urine when the waste is diminished to the natural amount by restoration of vital power, by due oxygenation of the blood, and by improved digestion and assimilation.

57. *v. CYSTINE, ITS PATHOLOGICAL RELATIONS.*—This substance does not exist in healthy urine, and rarely occurs in morbid urine. It is probably derived from the sulphur extractive of urine (§ 30). In its chemical composition it contains no less than 26 per cent of sulphur. Cystine, Dr. G. BIRD states, has been found in urinary sediments by very few observers, and it was not recognised in this form until a long period after its discovery in calculi by Dr. WOLLASTON. In the rare cases in which it has been observed, it formed a nearly white or pale fawn-coloured pulverulent deposit, resembling pale urate of ammonia. The greatest proportion of cystine may be inferred to be merely diffused in the urine while in the bladder, as at the moment of discharge the urine is turbid, and immediately deposits a copious sediment. Dr. G. BIRD states that, on apply-

ing heat to the urine, the deposit undergoes no change, and very slowly dissolves on the subsequent addition of hydrochloric or nitric acid. "Pure cystine is soluble in the mineral, and insoluble in the vegetable acids; with the former, it forms imperfect saline combinations, which leave by evaporation gummy masses or acicular crystals. It is readily soluble in ammonia and the fixed alkalies and their carbonates, but insoluble in carbonate of ammonia. Heated on platinum foil it burns, evolving a peculiar disagreeable odour." Cystine may be distinguished from a deposit of urate of ammonia by not disappearing on heating the urine, and from the earthy phosphates by being soluble in very dilute hydrochloric or strong acetic acid. "The best character of cystine is its ready solubility in ammonia, mere agitation of some of the deposit with liquor ammoniæ being sufficient to dissolve it; and a few drops of the fluid, when allowed to evaporate spontaneously on a slip of glass, leaves six-sided tables of cystine. The ammoniacal solution, when kept for some time in a white glass bottle, stains it black, from the combination of the sulphur of the cystine with the lead in the glass."

58 *a. The character of urine depositing cystine* is that of a pale yellow, or more of a honey-yellow than of an amber tint, presenting an appearance like diabetic urine. It is below the average specific gravity, is passed in larger quantity than usual, and is often neutral, seldom acid to litmus paper, and soon becomes alkaline. The odour of this urine is peculiar, and resembles that of sweet-brier. It is more rarely fetid, and when it is, the colour is generally greenish or greenish yellow. "A certain portion of cystine exists in solution in the urine, as the addition of acetic acid always precipitates a small quantity." Even when this deposit has vanished for some days together, crystals of cystine are then precipitated by acetic acid. Urea and uric acid are present in very small quantities, and in some instances the latter is nearly absent.

59 *b. Calculi* composed of cystine are generally pale yellow or fawn-coloured, but by long keeping they become greenish-gray, or a fine greenish-blue, probably owing to the action of light. The *microscopic characters* of cystine are very obvious. When it occurs as a deposit, it is always crystallized, never being amorphous. Among the crystals a few regular six-sided laminæ are often seen, but the great mass is composed of a large number of superposed plates, so that the compound crystals thus produced appeared multiangular; but I must refer the reader to Dr. G. BIRD's work, where this topic is well illustrated by wood-cuts.

60 *c. The pathological origin of cystine* is no farther known than that it is inferred to proceed from the waste of tissues, [especially the albuminous,] and probably also of the hæmato-globulin, or rather of some derangement of the normal course of this waste connected more especially with an excessive elimination of sulphur; every ounce of cystine containing more than two drachms of this element. Cystine may thus be formed from those elements of the tissues normally producing urea and uric acid with an excess of sulphur, owing probably to a deficiency of the process of oxidation in connexion with impaired vital energy. That these latter states obtain is evinced by the occurrence of cystine, or of cystin-uria, in scrofulous, chlorotic, and anæ-

mied subjects. The hereditary nature of this condition of the urine has been noticed by Dr. G. BIRD, who states that in one family alone several members were affected with cystin-uria; and that one instance exists in which it can be traced with tolerable certainty through three generations. In one case under the care of Mr. LUKE, extensive disorganization of the kidneys co-existed with a cystine calculus. Dr. PROUT has seen fatty matter mixed with the urine in cystin-uria, and suggests the probability of its connexion with fatty liver. Dr. G. BIRD thinks it not unlikely that the excretion of cystine may be a means, under certain circumstances, of compensating for deficient action of the liver *quoad* the excretion of sulphur. The existence of cystine in the urine of chlorotic and debilitated females has been met with in several cases by Dr. SHEARMAN, of Rotherham.

[According to our observations, *cystine* is not often met with in the urine of the human species, though very common in the dog. Dr. WOLLASTON called it *cystic oxide*, because peculiar to the bladder, and resembling some few of that class of substances in being soluble in both acids and alkalies. In calculi it exists in a perfectly pure form. It dissolves in dilute nitric, hydrochloric, sulphuric, oxalic, and phosphoric acids, but will not combine with the tartaric, acetic, or citric acids. It is dissolved by caustic ammonia, but not by the carbonate of that alkali; also by the fixed caustic alkalies and their carbonates. A dark brown colour is produced by evaporating nitric acid on cystine. It is insoluble in alcohol, and nearly so in water. The *carb. of ammonia* is the best precipitate for it, when in solution in acids, and the *acetic acid* from alkalies. The best mode of detecting cystine is to dissolve the calculous matter in caustic potash, then add a solution of acetate of lead in such proportions that the oxide of lead shall not precipitate, but be retained in solution by the excess of potash. This liquor becomes black when boiled, if cystine is present, a reaction dependent on the presence of sulphur in the cystine. Before the blowpipe it is consumed, yielding a very peculiar fetid smell. It may be easily distinguished from the other components of calculi by its being soluble in dilute hydrochloric acid, and a solution of *carb. of potash*.]

61. *d. Indications of Cure*.—Dr. PROUT advises the prolonged use of nitro-hydrochloric acid, and found it of benefit in some cases. Having viewed the existence of cystine in the urine as a result of debility in connexion with imperfect oxidation of the blood-globules, I have in one case prescribed the chlorate of potash with tonic infusions. This view of the pathology of cystine is suggestive also of the employment of the tincture of the chloride of iron, of the iodide of iron, of chalybeate mineral waters, and of other tonics, for its removal, aided by a generous diet, by active exercise in the open air, and by due attention to the functions of the skin and bowels. (See also the *Treatment of Debility*, of CHLOROSIS, and of SCROFULA.)

62. *vi. HIPPURIC ACID*—HIPPIURIA.—This acid is constantly present in the urine of the horse, and generally also in that of herbivorous animals.—*a.* LEHMANN found it in diabetic urine, and LIEBIG detected it in healthy urine, although in minute quantity. As this substance never appears as a sediment until after the addition of a stronger acid, the *diagnosis* of it entirely depends

upon the characters of the urine containing it. The urine containing an excess of hippuric acid is either very slightly acid, or neutral. It may be even alkaline. When this state of urine is caused by the ingestion of benzoic acid, it is then very acid. Its odour is commonly that of whey, and its specific gravity is below the healthy state, varying from 1.006 to 1.008. Deposits of the triple phosphate of magnesia are not infrequent in it. For the modes of detecting this acid, and for its microscopic characters, I must refer the reader to Dr. G. BIRD's work.

[To detect *hippuric acid*, evaporate a few ounces of urine to a sirupy consistence, then add an excess of hydrochloric acid, when a mixture of hippuric and uric acids will be separated and fall to the bottom of the vessel. After a few hours' repose, decant the supernatant fluid, and wash the deposit in a little very cold water; boil the residue with alcohol (in which uric acid is insoluble), when the hippuric acid will be dissolved, and, on evaporation, will be found in thin, delicate, strongly-coloured needles. Hippuric acid requires nearly 400 times its weight of cold water for solution.]

63. *b. The pathological states* causing this state of urine are not always obvious. In the lower animals it proceeds from vegetable food, it being constant in such as are not exercised, and replaced by benzoic acid in those that are worked. When in excess in human urine, it is ascribable to diet; thus it has been found after a prolonged milk diet, after an excessive use of apples, and in the urine of infants. This acid does not necessarily interfere with the production of uric acid, but generally it is attended by a deficiency of urea. It has been found in urine containing albumen. Dr. G. BIRD ascribes it to a diet deficient in nitrogen, or to the mal-assimilation of the carbon in the food, and infers "that hippuric acid may be one of the agents by which the kidneys perform a vicarious function for the liver, in removing an excess of carbon from the system." In this respect it may be viewed as an analogous result to the production of purpurine and bile-pigment, each removing 63.93, 62.0, and 68.18 per cent. of carbon, respectively, from the system. It should be looked for in the urine when the functions of the liver, lungs, and skin are defective, when the food is deficient in nitrogen, and when the urine is copious, is slightly acid or neutral, and of low specific gravity.

64. vii. **OXALATE OF LIME—OXALURIA.**—Oxalate of lime often exists in the urine, and is frequently a constituent of calculous concretions. Its chemical and pathological relations have been ably investigated by Dr. G. BIRD, who contends for its frequent appearance as a crystalline deposit in the urine, in fine and well-defined octahedral crystals, and for "the connexion between the occurrence of this substance and the existence of a certain series of ailments generally characterized by nervous irritability." He considers that the depressing influences, always present in densely populated cities, are more productive of this than of earthy phosphatic deposits; and that traces of oxalate of lime, in the minutest microscopic crystals, may be detected in the urine of persons free from any apparent disease. Hence he regards it as one of the common results of metamorphosis of tissue. But this is very different from its presence in large crystals and in considerable quantities, these constituting a truly pathological condition.

65. *a. For the detection* of oxalate of lime in the urine, I must refer to the work already quoted for the full details; generally, however, the existence of this substance may be ascertained by pouring off the upper six sevenths of the water passed a few hours after a meal, having given it time to repose in a glass vessel. A portion of the remaining seventh may be warmed in a watch-glass to dissolve the urate of ammonia. Having removed the greater part of the fluid, and replaced it by distilled water, a white glistening powder like diamond dust now becomes visible; and this under the microscope will be found to consist of crystals of oxalate of lime in transparent octahedra, with sharply-defined edges and angles. Dr. G. BIRD states that, out of a great number of specimens of urine containing the oxalate, it has scarcely ever appeared in the form of a distinct deposit, but has remained diffused in the urine, even when present in so large a quantity that each drop, when placed under the microscope, was loaded with its crystals. But if any substance capable of being a nucleus were present, the oxalate would be deposited around it, although scarcely in cohering masses, and invariably colourless and beautifully transparent. The oxalate of lime, although absolutely insoluble in water, must be soluble in urine, for its lustrous crystalline form sufficiently indicates its previous solution, and it is not until after the urine has been voided several hours that the crystals of oxalate can be detected.

66. Occasionally some remarkable crystals of the oxalate resembling *dumb-bells*, or two kidneys with their concavities opposed, are met with, their surfaces being finely striated. But it is doubtful whether or no these are an oxalate of lime. Dr. G. BIRD considers them an oxalurate of lime, a salt which differs from the oxalate in ultimate composition only in the presence of the elements of urea and absence of the constituents of water. Dr. BACON has investigated these crystals minutely, and has concluded that the dumb-bell crystals consist of a "salt of lime containing either oxalic, oxaluric, or perhaps some other organic acid easily converted into oxalic acid; but the exact nature of the acid remains to be determined by future examination."

67. *b. The characters of urine* containing the oxalate of lime are those of a fine amber hue, sometimes darker than in health, in a few cases paler than natural, and of a lower specific gravity, the odour being generally natural, or rarely aromatic like mignonette. Frequently a deposit of urate of ammonia, sometimes tinted pink by purpurine, falls during cooling. The specific gravity of oxalic urine varies extremely. Of 85 different specimens, Dr. G. BIRD found 9 in which it ranged from 1.009 to 1.015; in 27 from 1.016 to 1.020; in 23 from 1.021 to 1.025; and in 26 from 1.025 to 1.030. Generally the heaviest specimens contained most of the oxalate. The quantity passed seldom exceeded the average, instances of positive diuresis being rare. Irritability of bladder was sometimes complained of. Acidity of the urine was well marked, even more so than in health, and always present. An increase in the quantity of urea was frequently found. Mr. STALLARD discovered in oxalic urine a great increase of the indeterminate organic matters (§ 21), often as much as double the average proportion in twenty-four hours.

68. *c. The complications of oxalate of lime with*

other deposits are of some importance. Dr. G. BIRD found the oxalate of lime unmixed with any other saline deposits in more than one half of the specimens of oxalic urine. "In a very few, crystals of uric acid were found from the first, mixed with the octahedra of oxalate of lime; and in nearly all the successful cases this acid appeared in the course of treatment, and ultimately replaced the oxalate altogether," at a period generally contemporary with convalescence. "Much more rarely, prisms and stellæ of the ammoniaco-magnesian phosphate were found mixed with the oxalate, and occasionally replacing it in the course of treatment; and still less frequently, the phosphate was observed in the urine some time before the appearance of the oxalate." Very few well-marked instances of a complication of the oxalic-acid urine with granular degeneration of the kidneys were observed. Of the 85 cases referred to above (§ 67), 43 were unmixed cases of oxalate; 15 were cases of oxalate mixed with urate of ammonia; 15 were mixed with uric acid; 4 were mixed with triple phosphate; and 8 with phosphate deposited by heat. Dr. G. BIRD constantly found a very large quantity of epithelial cells and scales in oxalic urine, indeed so constantly, that a white deposit of epithelium led to the suspicion of the presence of oxalate of lime.

69. *d. The pathological source of oxalate of lime in the urine is of great interest.* It is well known that a physiological connexion exists between sugar and oxalic acid; that the former substance is a common constituent of our aliments; and that most of the farinacea are partially converted into this substance during digestion. Under certain circumstances the sugar thus formed is carried into the blood, and is eliminated by the kidneys. In certain morbid states, a large proportion of the food may be converted into sugar in the stomach, which passes rapidly into the circulation, and is excreted by the kidneys as diabetic urine.\* Recollecting the facility with which sugar and its chemical allies are, under the influence of oxidizing agents, converted into oxalic acid, it might be inferred that the existence of oxaluria is due to the presence of sugar in the blood. Dr. G. BIRD, however, argues against any connexion or relation subsisting between oxaluria and diabetic urine, inasmuch as sugar very rarely exists in the former; and as the latter rarely contains, in a given quantity, an

excess of urea, uric acid, or urates, and is remarkably free from saline deposits, the high specific gravity depending upon the large proportion of sugar. In oxaluria, on the other hand, a large excess of urea, of uric acid, and urates is present, and is as characteristic of this state of urine as the oxalate of lime itself. Hence he infers that there is no relation between oxalic acid and saccharine urine. From the symptoms present in cases where oxaluria is observed, there can be no doubt that the primary cause of this state of urine must, as Dr. PROUT has shown, be imputed to an unhealthy condition of the digestive and assimilating functions. That the oxalic acid is formed from its elements, either in the digestive canal or in its course to and in the blood, must be inferred, since Dr. GARROD detected, beyond any doubt, octahedral crystals of oxalate of lime in the serum of blood from a patient affected with albuminuria. "It is difficult to explain the presence of so insoluble a salt in solution in the blood; but it is probable that the opinion of Dr. SCHMIDT, of Dorpat, may be correct. He has assumed that there exists in the animal economy a tendency to the formation of a soluble triple compound of oxalic acid, lime, and albumen, which, by its decomposition, allows oxalate of lime to crystallize." Probably such a compound exists in the blood in disease; and when the acetic acid is added, as in Dr. GARROD's process, the albumen is separated and the oxalate set free.

70. The chemical relation existing between uric acid, urea, and oxalic acid, and the readiness with which the former of these substances is convertible into the latter, suggest the idea that oxaluria may be regarded as a form of what has been termed by Dr. WILLIS *azoturia*, of which an excess of urea is the prevalent indication, part of the urea, or of its elements, having been converted into oxalic acid. It may be inquired, Whence are the elements which form oxalic acid? Are they derived from the metamorphic changes of the structures, like healthy urea and uric acid? Dr. G. BIRD infers that they are "Hence oxalate of lime must be regarded as one of the common results of metamorphosis of tissue." (*Op. cit.*, p. 210.) I am more disposed to agree with the opinion he has subsequently stated, viz., that although it is probable that such may be the origin of oxaluria (in the waste of the tissues), yet, the quantity of oxalate of lime being greatest after a full meal, and often absent in the urine passed in the morning, frequently disappearing when the diet is regulated, and reappearing on the use of unwholesome food, it is equally probable that this salt is derived from the mal-assimilated elements of food. It is sufficiently obvious, from the nature of the complaints in which oxaluria occurs, that it is always the result of imperfect assimilation of the aliments, owing to impaired organic nervous power, the mal-assimilated, or rather the non-assimilated, elements forming the product in question, aided by oxidation, which product is rather eliminated than formed by the kidneys. However minute and laborious may be the researches of organic chemists in endeavouring to show the elementary combinations and the atomic affinities of these elements, in the production of urinary deposits, the vital endowment, and the states of function depending upon this endowment, more especially demand attention; the chemical constitution of the urine being generally only a sign, but an

[\* The best tests for sugar in the urine are *Frommer's*, *Capezzuoli's*, and *Moore's*. *Frommer's Test*.—Add to the suspected urine, in a large test-tube, just enough of a solution of sulphate of copper to communicate a faint blue tint; a slight deposit of phosphate of copper generally falls. Then add *liquor potassæ* in great excess; a precipitate of hydrated oxide of copper first falls, which redissolves in the excess of alkali, if sugar be present, forming a blue solution like ammoniuret of copper. On gently heating the mixture to ebullition, a deposit of red sub-oxide of copper falls, if sugar be present.

*Moore's Test*.—Place in a test-tube about two drachms of the suspected urine, and add nearly half its bulk of *liquor potassæ*. Heat the whole over a spirit-lamp, and allow actual ebullition to continue for a minute or two; the previously pale urine will become of an orange-brown, or even bistre tint, according to the proportion of sugar present.

*Capezzuoli's Test* consists in adding a few grains of hydrated oxide of copper to urine contained in a conical glass vessel, and render the whole alkaline by adding *liquor potassæ*. If sugar be present, the fluid assumes a reddish colour, and in a few hours the edge of the deposit of oxide assumes a yellow colour, which gradually extends through the mass, from a reduction of the oxide to a metallic state (sub-oxide?)]

important one, of the state of this endowment, particularly as manifested by the organic nervous system.

71. *e. The symptoms accompanying the excretion of oxalate of lime* have been minutely described by professors of the urinary specialty; and conformably with the importance they attach to an urinary deposit, they view it as the actual disease, or at least as a diathesis, instead of being merely a sign, or at most a result, of pre-existing disorder or disease, to which more especially rational medication should be directed. Oxaluria is not a sign of one, or even of two disorders merely, but of several, the chief morbid manifestations being depressed vital endowment of the digestive and assimilating organs, with lowness of spirits, irritability or nervousness, hypochondriacal feelings, impaired nutrition, anæmia, and often loss of sexual power. Pains in the loins, irritability of bladder, and high specific gravity of the urine—generally from 1.025 to 1.030—with various symptoms of impaired health, are also commonly experienced. The urine is invariably acid, often excessively so; and there is a marked tendency to eruptions of boils. Dr G. BIRD remarks that he has seldom met with phthisis in cases with oxalate of lime deposit, and that in very few instances has he seen oxaluria terminate in the formation of a calculus. He again states that the source of this deposit is to be imputed to metamorphosis of the tissues, and that this is the only way that the attending emaciation can be satisfactorily accounted for. I have already stated my belief that this deposit as well as the emaciation are the results of impaired or morbid assimilation of the food, and the consequent imperfect nutrition of the tissues (§ 70).

72. *f. Causes.*—This state of the urine is frequent in those who are subject to mental anxiety and to laborious mental occupations, more especially in men on the stock-exchange, in medical men, in barristers and solicitors, and in those who are engaged in occupations attended by much mental anxiety, and are excessively devoted to business or study. The *exciting causes* are chiefly neglect of health, chronic dyspepsia, hypochondriasis, exhaustion from disease, from syphilis or mercurial courses; venereal excesses, masturbation, involuntary seminal emissions, excessive discharges, and prolonged lactation, previous acute diseases, injuries affecting the spine, &c., &c.

73. *g. The treatment of oxalate of lime deposits* is generally successful, if the diet and the regimen of both mind and body be duly regulated. The food should be digestible, properly cooked, and the animal and vegetable in due proportion. Malt liquor ought to be avoided; and either a small quantity of brandy in much water, or a glass of dry sherry in two of water, may be taken with dinner. The medicines most appropriate are the nitric or nitro-hydrochloric acid (one part of the nitric to two of the hydrochloric) given in tonic infusions or decoctions. If anæmia or chlorosis exist, the tincture of the muriate of iron, with preparations of calumba or quassia; or the *mistura ferri composita*, or the ammonio-citrate or ammonio-tartrate of iron, should be prescribed. If the bowels be costive, the extract of taraxacum may be given with the former medicines; or the decoction of aloes be conjoined with the *mistura ferri composita*; or the *mistura*

*gentiana composita* may be given alone, or with tincture of serpentaria, &c. The sulphate of iron, or of quinine, or of zinc may be prescribed, where the foregoing fail, combined with small doses of camphor and henbane, or of conium. Dr. G. BIRD recommends recourse to colchicum for oxaluria, and states that, under the influence of this drug, copious deposits of oxalate of lime have become replaced by uric acid and the urate of ammonia, thus inducing a condition of urine much more amenable to treatment.

74. viii. *CHEMICAL PATHOLOGY OF EARTHY SALTS IN THE URINE.*—*Phosphuria*—*Phosphate of Lime, Ammonio-phosphate of Magnesia, and Carbonate of Lime.*—Phosphoric acid is excreted in considerable quantity from the blood by the kidneys, combined with soda, ammonia, lime, and magnesia; forming, most probably, ammonio-phosphate of soda, phosphate of magnesia, phosphate of lime. The first of these is soluble in water, and Dr. G. BIRD considers it to be the solvent of uric acid, and indirectly the source of the acidity of urine. The other two salts are insoluble, but the presence of a minute portion of an acid, even the carbonic, enables water to dissolve a considerable quantity. They are also soluble to some extent in hydrochlorate of ammonia. "In healthy urine, the earthy phosphates are held in solution by the acid of the super-phosphates, produced by the action of uric (or hippuric) acid on the tri-basic alkaline salts; and these salts are also, according to ENDERLIN, capable of dissolving a certain quantity of phosphate of lime." The earthy phosphates are always abundant after a meal, the reverse applying to the alkaline salts. Phosphoric acid may be excreted in large excess without forming a deposit, owing to its combination with an alkaline base; and hence, when the excretion of an excess of this acid is looked for, it is not indicated by the amount of earthy salts deposited, for there "is always three or four times more phosphoric acid in a given specimen of urine, in the form of a soluble alkaline salt, than is precipitated as an insoluble earthy compound. The presence of an excess of lime and magnesia has more to do with determining a deposition of insoluble phosphate than an excess of phosphoric acid." The circumstances under which the earthy phosphates are deposited often are of so great importance as to require a recognition of their existence, as well as of the quantities of these phosphatic deposits.

75. *A. The Diagnosis of earthy Phosphates.*—*a.* Deposits of these phosphates are white, unless coloured with blood, are soluble in dilute hydrochloric acid, and insoluble in liquor potassæ and in ammonia. On heating the urine, the deposit merely agglomerates into little masses. A small quantity of a solution of sesqui-carbonate of ammonia added to a large quantity of healthy urine causes turbidity, from a deposit of the triple phosphate mixed with some phosphate of lime. "On placing a drop of this turbid urine under the microscope, myriads of minute prisms of the triple salt, mixed with amorphous granules of the phosphate of lime, will be seen floating in the fluid; these disappear on adding a drop of any acid. As these earthy salts are insoluble in water, they must be held in solution in the urine by the free acid which generally exists. If from any cause the quantity of solvent acid falls below the necessary proportion, the earthy phosphates

appear diffused through the urine, disturbing its transparency, and subside, forming a deposit. Hence, whenever the urine is alkaline, phosphatic deposits are necessary consequences. If urine be secreted with so small a proportion of acid as barely to redden litmus paper, a deposit of triple phosphate often occurs within a few hours after emission; probably owing to the presence of mucous matter, which induces the decomposition of urea and the formation of carbonate of ammonia, which, by neutralizing the solvent acid, precipitates the phosphates. The triple phosphate, which occurs spontaneously in prismatic crystals, is a neutral salt, "and may coexist as a deposit with very sensible acidity of the supernatant urine. It by no means follows that the existence of a deposit of this salt involves the necessarily alkaline state of the urine." Another triple phosphate, differing from the former in containing an excess of base, is of frequent occurrence in the urine when in an alkaline or putrescent state. It cannot be present in urine having the slightest acid reaction on litmus paper. Its crystals are invariably stellar or foliaceous. This salt is termed the basic phosphate. "When the triple or calcareous phosphates are separately exposed to the heat of a blow-pipe flame, they fuse with great difficulty, and not until the heat has been urged to the utmost. If, however, the phosphate of lime is mixed with a triple phosphate in about equal proportions, they readily melt into a white enamel. These mixed salts constitute what is hence termed the fusible calculus, and they can readily be detected by this property in concretions; a character very available in the examination of gravel and calculi, as the two phosphates generally occur together."\*

76. *b.* The physical appearance of deposits of the earthy phosphate varies remarkably. Sometimes they appear as a white crystalline gravel, especially when the triple salt is the chief part of the deposit. But if a small quantity be present, it may readily escape detection by remaining a long time diffused in the urine. After a repose of a few hours, some of the crystals collect on the surface, forming an iridescent pellicle, "reflecting coloured bands like a soap-bubble or a thin layer of oil. If then the lower layers of the urine be placed on a watch-glass, and held obliquely over the flame of a candle or any strong light, a series of glittering points will become visible from the reflection of light from the facets of the minute prisms of the salt." (*Op. cit.*, p. 269.)

77. The phosphates often subside to the bottom of the vessel like a dense cloud of mucus, for which they may be mistaken. Sometimes they form, in very alkaline urine, dense masses, hanging in ropes, like the thickest puriform mucus, from which it is impossible to distinguish them by the unaided eye. Their disappearance on the addition of hydrochloric acid shows at once their nature. The examination of a few drops of the urine between two plates of glass, by the microscope, will detect the characteristic crystals of

the phosphates. Occasionally they are mixed in a deposit with the urate of ammonia, this latter being pale or nearly white. As phosphatic urine is usually very pale, it follows that any urate of ammonia deposited from it will be nearly white from the absence of colouring matter.

[*Microscopic Characters.*—According to BIRD, the neutral triple phosphate occurs: 1st, in well-defined colourless prisms, the angles and edges of the crystals being remarkably sharp and perfect. The triangular prism is most frequently met with, but it presents every variety of termination, sometimes merely truncated, often bevelled off, and not unfrequently the terminal edges are replaced by facets, presenting a very beautiful microscopic object of great transparency, or of an enamel-like opacity, so that they can only be viewed as opaque objects; 2d, the triple phosphate forms minute calculous concretions, composed of colourless acicular prisms, cohering at one end, so as to represent simple *stellæ*, or *rosettes*; 3d, *Penniform crystals*, resembling *striated feather-like crystals*, two being often connected, so as to cause them to resemble wings; 4th, *Stellar and foliaceous crystals*. Dr. BIRD regards this as usually a secondary product taking place out of the body, generally occurring in the form of *six-rayed stars*, each ray being serrated, or irregularly erenate, resembling a taraxacum leaf.]

78. *c.* *States of Phosphatic Urine.*—Although it may appear necessary for the urine to be alkaline for a deposit of phosphates to exist, yet generally urine which deposits the triple phosphate is acid at the time of its excretion. Some neutral salts redden litmus paper, and yet contain no free acid; and this fact may in some cases explain the occasional acid reaction where deposits of phosphates exist. Dr. O. REES has shown that hydrochlorate of ammonia may in some cases be the solvent of the earthy phosphates when in excess. Occasionally urine does not contain any visible deposit, and yet on the application of heat appears to coagulate from the deposition of earthy phosphates. The addition of a drop of nitric acid immediately dissolves this deposit, and distinguishes it from albumen. The precipitation of the earthy phosphates by heat has been ascribed by Dr. H. BRETT to the existence of carbonic acid in the urine in a free state. Dr. B. JONES has, however, shown that, if to any urine rich in phosphates, as that passed shortly after a meal, a minute portion of an alkali be added to neutralize any great excess of acid, the subsequent application of heat precipitates the earthy phosphates.

79. Generally, where phosphatic deposits, magnesian, calcareous, or both, exist for a considerable time, the urine is pale, often whey-like, passed in large quantities, and of low specific gravity—from 1.005 to 1.014. "This is especially the case where organic lesion of the kidneys exists." On the other hand, when the deposits recur and disappear in the course of a few days, the urine is generally of a deep amber colour, is of high specific gravity (from 1.020 to 1.030), often contains an excess of urea, and presents an iridescent pellicle on its surface by repose. This form of phosphatic urine is often met with in connexion with irritative or inflammatory dyspepsia and with mal-assimilation. Sometimes prisms of triple phosphate are seen entangled in the meshes of a mucous cloud for a day or two, and then disappear. Phosphatic

\* Some writers speak of calculi composed of the "acid phosphate of lime." By this is meant, not the super-phosphate, but the neutral or di-phosphate of lime. When the di-phosphate of lime *calculus* is digested with water, it is decomposed into an insoluble sub-phosphate and a soluble super-phosphate, which possesses an acid reaction; and this fact led FOURCROY into the mistake of describing these concretions as composed of a super-phosphate of lime. Di-phosphate of lime constitutes the accidental bezoar, an intestinal concretion found in the stomach of the ox, deer, &c.].

urine occasionally varies from a whey-like hue to a deep brown or greenish brown, is very fetid, generally alkaline, "and loaded with a dense ropy mucus often tinged with blood, and in which large crystals of the triple phosphate and amorphous masses of phosphate of lime are entangled. This variety is almost always met with, either under the irritation of a calculus, or even of a catheter worn in the bladder," or where actual disease of the mucous coat of this organ exists.

80. *d.* For the *microscopic characters* of earthy phosphates, I must refer to Dr. G. BIRD's work, where they are fully illustrated. I can only mention, 1st, the *prisms of neutral triple phosphates*; these are well defined, the triangular prism being the form most frequently met with, but it presents every variety in its terminations; 2d, *simple stella of the neutral salt*, the radii being more or less distinct or crowded; 3d, *peniform crystals of neutral salt*; this variety presents the appearance of striated feather-like crystals, two being generally connected, resembling a pair of wings; 4th, *stellar and foliaceous crystals of basic salt*; this variety is chiefly formed after the urine is discharged, and, when rapidly formed, it generally appears as six-rayed stars, each ray being serrated. *Phosphate of lime* generally presents no appearance of crystalline structure; it either resembling an amorphous powder, or being collected in rounded particles, often adhering to prisms of triple phosphate.

81. *B. Pathological Relations of the Phosphates.*—I have many years ago contended, and more recently, in various parts of this work, alluded to the fact, that the *secretions* are endowed, to a certain extent, with an emanation of vitality which for a time resists the changes which they are disposed to enter into, either when organic nervous influence is much depressed or when they are removed from the body. "Indeed, the vital influence modifies their physical conditions, in a more or less marked manner, as long as they continue subjected to its operation. From this source, also, they are imbued with a vital emanation, the presence of which is indicated by the continuance, for a time, of the specific characters of each. This emanation, being no longer required when they are removed from the body, is soon dissipated. The secretions, while within the sphere of the animal system, and for a short time afterward, possess this emanation of the vital influence, to an amount sufficient to give them certain characters, and to preserve them from the chemical changes to which their constituents are naturally prone; but when this influence becomes depressed, or ultimately ceases, they then undergo dissolution as unequivocal as that evinced by the textures of the body. In confirmation of this view, I need only refer to the comparative conditions of the more perfectly elaborated secretions immediately after their formation and excretion, and after periods of various duration have elapsed from the time of their discharge from the body." (*Physiol. Notes by the Author*, p. 636.)

82. The above doctrine was published by me in 1824; and both then and subsequently I have insisted upon its importance, and upon the obvious deductions which follow from it. While vital energy is perfect, or at least not materially impaired, the secreted fluids, especially while they remain undischarged from the body, are pre-

served by this emanation of vital influence from those changes to which their constituents are chemically disposed. But if these fluids are retained for an unusually lengthened period, or if vital energy, to which they owe their original natural character, be much impaired, those changes which their constituents are chemically disposed to undergo take place more rapidly after their discharge from the body, and in many instances even while they still remain in those receptacles or cavities which are provided for their reception and temporary retention. But with the various manifestations of depressed vital power, changes in the secretions are not only such as take place after these secretions are produced, but also those which occur during their production, and which depend upon the existing state of vitality throughout the body, and upon the manifestations and modifications of vitality in the organs especially destined to the formation of these secretions. When vital energy is impaired, or, in other words, when debility is manifest, whether constituting the only or chief pathological condition or associated with others, as with nervous susceptibility or irritability, or with febrile action, or with organic change, or with other alterations farther impeding or disturbing the functions of a secreting organ or organs, results, will be furnished by the secretions varying with the manner in which the general impairment of vital power affects the functions of digestion, assimilation, nutrition, and waste—the successive conditions of nutritive supply, of vital cohesion and resistance, of molecular dissolution, of vascular depuration, and of ultimate discharge.

83. This doctrine, which, as I have shown, has been published and taught by me with reference especially to the several secretions and excretions—recrementitious, excrementitious, or depurating—is altogether applicable to the urinary excretion, and to the deposits which form in it, both after and previous to its discharge from the body, and in a more particular manner to the urine which furnishes the phosphates in great or unusual excess. The deposit of earthy phosphates may be viewed as resulting more especially from depression or exhaustion of vital power, as manifested chiefly by the nervous system, and is hence most frequently met with in the aged, and in those who labour under disease of the cerebro-spinal nervous system, or have experienced injury of the spine, or have suffered much from tear and wear of mind and body. The pathological conditions giving rise to the deposits of phosphate of lime are similar to those producing the triple salt. Indeed, they often occur simultaneously, especially when the urine is alkaline. Dr. G. BIRD considers that, when the deposit has consisted chiefly of the calcareous salt, the patients have presented more marked evidence of exhaustion, and of the previous existence of some drain on the nervous system, than when the triple salt alone existed, unless its source is strictly local.

84. When the triple phosphate occurs in small quantities, nearly or quite free from the phosphate of lime, the urine being acid or neutral at the time of emission, the cases are then the slightest of this class of disorders. Nevertheless, severe dyspepsia, irritability, restlessness, impaired assimilation, and emaciation are constantly present. When there is an excessive discharge of urea, the symptoms are more severe, and the exhaustion and nervous depression greater. The urine

is then of a rich amber colour, generally depositing phosphates on the application of heat, and of a specific gravity varying from 1.025 to 1.030. In mild cases of dyspepsia, especially in the gouty diathesis, an iridescent pellicle of triple salt, the urine being rich in urea and either acid or neutral, is often observed. This state of the urine is not infrequent in dyspeptic females at or about the climacteric period. Crystals of the triple salt occur in very old persons, especially in the ill-fed; in persons recovering from acute diseases, especially from rheumatic fever.

85 Early in continued fever the urine is high-coloured, and loaded with uric acid and urates. It is then generally acid, but after the end of the second week, or earlier, in the lower types of fever, the acidity often vanishes, and the urine becomes *alkaline* and deposits the phosphates. This is, however, more frequently seen in some types and states of fever than in others, especially in the typhoid and putro-adynamic, and when comatose symptoms appear. The treatment, particularly the use of alkaline medicines, or of the salts of the vegetable acids, has some influence in favouring the change to an alkaline state of the urine. In these cases, as well as in other diseases where the nervous energy is remarkably depressed or exhausted, more especially in the low forms of insanity, in cases of debility from venereal excess, masturbation, &c., after injuries of the spine, as remarked by PROCT, BROUÉ, and others, the elements of urea become rearranged, or obedient to ordinary chemical affinities, and form carbonate of ammonia.

86 When the deposit of phosphates is copious, the two phosphates are generally mixed, either falling to the bottom of the vessel, or remaining suspended in the urine like mucus: the urine is then generally alkaline, and the odour ammoniacal or fetid. This kind of urine is most remarkable in organic disease of the urinary organs, or serious affections of the spinal cord followed by such disease. Conformably with the doctrine above insisted upon (§ 81-5), the impaired vitality of these organs depending upon depressed vitality of the frame generally, as in typhoid and putro-adynamic fevers, or of the urinary organs especially, as after injuries or diseases of the spine, its cord, &c., so affects the urinary secretion, both during the performance of this function and while the secretion is retained, as to favour the occurrence of those changes, even before it is discharged, which its ordinary chemical affinities dispose it to assume. The change thus produced in the urine may be followed by the formation of calculi in any part of the urinary apparatus, but most frequently by irritation of the urinary mucous surfaces and by the secretion of a quantity of viscid mucus, which may become puriform or changed, by the carbonate of ammonia formed in the urine, into a viscid and almost gelatinous or tenacious ropy fluid, sometimes preventing the discharge of the urine, and increasing the sufferings of the patient. Mr CURLING's view of this subject is different from that now stated. He believes that the result of the spinal lesion is the loss of the natural sensibility of the bladder. The effect of this is the secretion of unhealthy alcalescent mucus, which acts chemically upon the urine, renders it alkaline, and leads to the deposition of the earthy phosphates. He thinks that the urine may subsequently be secreted in an alkaline state by the extension of the irritation from

the bladder to the kidneys, or by the latter sympathizing with the former. It should not, however, be overlooked, that injury of the spine not only deprives the urinary apparatus of that share of nervous power reinforcing the organic or ganglionic nervous influence which endows this apparatus, but thereby also modifies the secreting function of the kidneys. Whether the result be impairment only, or a modifying action also, there can be no doubt that the chief result of these injuries is paralysis of the bladder, especially as respects its contractile powers, causing retention of the urine, which, whether it be secreted in an altered or morbid condition, or rendered such after its secretion, owing to impaired vital influence, more readily irritates the urinary mucous surface than in its healthy state, and gives rise to mucous discharge and the consecutive lesions of the urinary organs.

87 The urine may be alkaline and loaded with phosphates, owing to disease of the *Urinary Bladder* (see that article), more especially of its mucous surface. This state of the urine thus arises from three important pathological conditions: 1st, from vital depression, as manifested chiefly by nervous debility and irritability; 2d, from injuries and diseases implicating the spinal cord or its membranes; 3d, from disease of the urinary organs. But it should not be overlooked that the second condition affects the urine by first disordering the functions and subsequently the structure of these organs. It is important to be able to distinguish between these sources of alkalinity of the urine, especially between the presence of a general morbid condition and a strictly local disease. Dr BENCE JONES has established that urine is alkaline from ammonia when the cause is local, and from a fixed alkali when the ailment is general. Hence urine may be alkaline, and not ammoniacal, although when the latter it is necessarily the former. The urine is sometimes alkaline after breakfast, owing to the presence of a fixed alkaline carbonate. The urine, in such cases, turns red litmus paper blue, whatever may be the alkali present; but if it be a fixed alkali, the paper remains blue after being dried before the fire; but if it be the volatile alkali, the paper resumes its red tint when thus exposed. When the urine is alkaline from ammonia, Dr. B. JONES has farther shown, abundant crystals of triple phosphate are always found, while, when ammonia is absent, these crystals are rarely present, and are replaced by a copious and dense deposit of phosphate of lime. He has arrived at the following conclusions as to the relation borne by phosphatic salts to certain pathological states:

88. 1st. No determination of an excessive secretion of phosphatic acid can be furnished by the deposit of earthy salts, unless the quantity of lime and magnesia in the food be taken into account; 2d. No *real increase* of phosphatic salts occurs in spinal diseases, notwithstanding the existence of deposits; 3d. In fever and in most acute inflammations, the phosphatic salts are not increased; 4th. In old cases of mania, melancholy, paralysis of the insane, or in chronic diseases in which nervous tissues are influenced, no conclusions can be drawn; 5th. In fractures of the skull, the phosphatic salts increase only when any inflammatory action occurs in the brain, and in acute phrenitis an excessive increase takes place; 6th. In delirium tremens there is a marked deficiency of phosphates, unless they are introduced with

the ingesta; an excess is, however, met with in some functional affections of the brain.

89. In some instances the urine is copious, pale, and freely deposits the phosphates, the patient being emaciated, and the urinary organs free from disease. In these the formation of a calculus may be dreaded. But when this does not exist, it will often be found that *tabes dorsalis* from masturbation is the cause both of the constitutional and of the urinary disorder. Dr. GOLDING BIRD states that the deposits of phosphates, where no organic disease exists, are often absent, not only for hours but for days together; and this fact will often indicate a favourable termination of the case; and he comes to the following conclusion: "that, where the presence of a deposit of phosphates is independent of the irritation of a calculus, or of organic disease, it is most abundant in the urine passed in the evening, and absent or replaced by uric acid or urates in the morning, the urine being always of a tolerably natural colour, never below, and often above the mean density. Where the presence of phosphatic salts depends upon the irritation of a calculus, or upon organic mischief in the urinary passages, the urine is pale and whey-like, of a density below the average, often considerably so, and the earthy deposit is nearly equally abundant in the night and morning urine." (*Op. cit.*, p. 293.)

90. *C. Therapeutical Indications.*—a. When phosphatic deposits depend upon *irritative dyspepsia*, or upon *nervous or febrile disorder*, independently of affection of the spine or of the urinary organs, the treatment should be directed rather to the constitutional, digestive, and assimilative disorders, than to the state of the urine, which ought to be viewed only as a symptom. In these cases, depression of spirits, hypochondriasis, and various dyspeptic symptoms, are present; and the urine has a high specific gravity, contains an excess of urea, and deposits crystalline or amorphous phosphates. In these the urinary deposits should be viewed as the results of defective vital and nutritive powers, and as exhausting the nervous energy; and the treatment ought to be directed to the functions of the stomach and bowels, and to the improvement of the general health, by means of stomaehic or tonic aperients, by a light, digestible, and generous diet, and by bitter infusions or decoctions. To remove the more painful symptoms, the oxide of bismuth or of zinc may be given with the extract of ox-gall, and the extract of henbane or the pil. saponis composita. In these cases the means advised in the articles *DEBILITY*, *HYPOCHONDRIASIS*, *INDIGESTION*, &c., will generally be appropriate.

91. *b.* When the *phosphatic deposits* depend upon *exhaustion or injury of the spinal cord*—upon *tabes dorsalis*, &c., then the medical means require modification. In these, great emaciation, copious phosphatic deposit, the phosphate of lime predominating remarkably, pain and weight in the lumbar region, copious pale urine and low specific gravity, and dryness of the skin, require not only the restoratives and tonics already advised, but also a recourse to opiates, conjoined with aromatics, diaphoretics, &c.. When these cases proceed from a blow or other injury of the spine, or wrench of the back, then the terebinthinate liniments or embrocations along the spine (see Form. 296, 311), the cold salt-water douche on the loins, followed by frictions or liniments, the emplastrum roborans, &c., will be of great

service. In many of these (especially when caused by masturbation) the preparations of iron, the nitro-muriatic acid in tonic infusions, the tincture of sumbul or of musk, or of serpentaria, with tincture of opium, are severally productive of more or less benefit. In mild and prolonged cases of this kind, a calculus is not unfrequently insidiously formed in the pelvis of the kidney. For these, the mineral acids have been recommended, as they hold the phosphatic salts in solution: of these, nitric or nitro-muriatic acid may be preferred; but it has been doubted whether they reach the kidneys or act upon the deposit. However, when given judiciously or conjoined with bitter tonics, they improve the general health, and thereby either prevent or arrest the increase of the deposit.\*

[Believing, with Dr. PROUT, that a perfectly healthy condition of the urine is not only one of the most natural, but probably also one of the most powerful solvents for all the ingredients likely to exist in urinary calculi that we can hope to possess, and that there is scarcely any form of stone that will long bear the continued action of healthy urine without becoming more or less dissolved or disintegrated, we direct the patient to drink very largely of pure rain-water, sometimes aiding the diuretic effect by parsley-root tea, infusion of juniper, the cucurbitaceous seeds, &c., in order to a copious secretion of healthy urine. Urinary deposits are often thrown down from the amount of urine being too small to hold them in solution; increase the quantity secreted, and the urine again becomes limpid and free from sediment. Great water-drinkers, as BOUCHARDAT says, are never afflicted with urinary calculi.]

92. *c.* When *phosphatic deposits* proceed from *lesion of the urinary organs*, their connexion with a morbid secretion from the mucous membrane of the bladder is well known. The disposition of the phosphates to adhere to this surface generally increases the difficulty of treatment. For this state of phosphatic cystitis, weak acid injec-

[\* BERZELIUS believed that he had proved by his experiments that the mineral acids never reach the kidneys in a free state, and never increase the acidity of the urine. This is doubtless the case generally with the vegetable acids also, which undergo decomposition or combustion in passing through the circulation. It certainly is very difficult to acidify alkaline urine. ORFILA, however, states that he detected *nitric, sulphuric, hydrochloric, oxalic*, and perhaps *acetic* acid in the urine of dogs poisoned by these acids, but never in a free state. WOLLER concludes from his experiments that *oxalic, tartaric, and benzoic* acids (and probably, therefore, *all acids*) are never eliminated in the urine in a free state, but always in combination with a base. Dr. BENCKE JONES states that, in his experiments with *sulphuric acid*, given freely many days in the form of lemonade, it does, after a while, pass off with the urine; but 254 grs. of dry *tartaric acid*, given after eating, were not sufficient to render the urine acid. Changes, however, in the condition of the digestive and assimilative organs readily affect the urine, as in the experiment of BERZELIUS, where he gave phosphoric acid freely for a considerable time without acidifying the urine; but as soon as it purged the patient, the urine lost its alkalinity, and deposited *uric acid*. Mr. BEANDE states very truly that, when mineral acids are given to relieve phosphatic deposits, they are apt to induce *red gravel* (uric acid); that the vegetable acids are less apt to cause the deposition of red gravel in the urine than the mineral ones. We conclude that all acids are very uncertain remedies in phosphatic gravel or calculi; that, at best, they are only palliative; and that, for the most part, when they do prove beneficial, it is by a tonic influence on the digestive organs and improving the functions of assimilation. When employed, it should always be in conjunction with the bitter tonics.]

tions into the urinary bladder have been advised, in order to wash away the phosphatic formation. A few drops of the hydrochloric acid, with as many of the *vinum opii* in tepid barley-water, may be injected daily. Dr. G. BIRD advises, in almost every case where phosphatic alkaline urine exists, to wash out the bladder by injections of warm water. (See also the treatment of *muco-cystitis* in *art. URINARY BLADDER*, § 89-97.)

93. ix. DEPOSITS OF CARBONATE OF LIME.—Carbonate of lime sometimes occurs in small proportions in deposits of earthy phosphates, when the urine is decidedly alkaline, owing to the decomposition of the phosphate of lime by the carbonate of ammonia which replaces the urea. Its appearance is that of an amorphous powder; and its presence may be recognised by the addition of any dilute acid, which dissolves it with effervescence; but the deposit should be previously washed to deprive it of any adherent carbonate of ammonia.

94. x. DEPOSITS OF BLUE OR BLACK MATTERS.—Certain colouring matters, communicating to the urine a blue or black tint, the products of diseased action, are met with on rare occasions. Three blue pigments, viz., cyanurine, indigo, and peryanide of iron; and two black, melanurine and melanic acid, have been distinguished. These colours, as well as green, have been mentioned by many of the older writers noticed in the *bibliography*, and have doubtless been owing to the presence of blood or bile altered by the urine. —(a) *Cyanurine* was discovered by BRACCONNET, and noticed by several more recent observers. Urine containing it is of a deep blue colour, the colouring matter being deposited by rest, and readily separated by the filter. The origin of this substance, as well as its pathological indications, if any, are obscure, and merely furnish a subject of conjectural discussions to chemical pathologists.

95. (b) *Indigo* is sometimes prescribed empirically in some diseases, as epilepsy; and it may thus pass into the urine, and form a blue deposit. PROUT and SIMON have shown that it may be generated in the economy, the urine acquiring a dark blue colour, and depositing a substance of the same hue, which, when collected on a filter, presents all the characters of indigo. The origin and pathological indications of this substance, when not taken internally, are unknown.

96. (c) *Prussian blue*, or *sesqui-ferro-cyanide of iron*, has been found in the urine after taking the ferro-cyanide of potassium upon preparations of iron. It furnishes no pathological inferences.

97. (d) *Melanurine and melanic acid* are black pigments which have been rarely met with in the urine. It is probable that they are merely the colouring matters of the blood altered by the state of the urine. Many years ago a clergyman in London, with whom I was well acquainted, experienced a dangerous immersion in the river, and was saved with difficulty. He soon afterward began to pass black urine, for which I was requested to visit him. He complained only of a slight weight in the region of the kidneys. The urine was quite black, was passed in about the usual quantity, and was retained nearly the usual time. The lower extremities were not affected. A portion of the colouring matter was deposited, but the supernatant urine was not materially altered from its black colour. I attributed the colour to the escape of red globules of blood with

the urine, owing to congestion of the kidneys, and their alteration by the state of the urine. Conformably with this view, I directed blood to be taken from the loins by cupping. The urine soon afterward resumed its healthy appearance, and no farther complaint was made.

98. xi. ORGANIC DEPOSITS IN URINE.—The deposits in the urine which have been noticed above are recognisable by their forms and chemical properties; those which remain to be mentioned either possess or have possessed organization, and can be distinguished only by an examination by means of the microscope or of tests.

99. A. BLOOD AND ITS ELEMENTS are often seen in the urine, and suggest important pathological and therapeutical indications. The urine may contain only the serum of the blood, or liquor sanguinis; or with this a considerable proportion of red globules; or it may contain a very large proportion of blood, hardly or not at all changed from its normal characters.

100. (a) *Serous or albuminous urine* is readily indicated by heat, and by adding a drop of nitric acid, which coagulates the albumen contained in it. Urine containing much albumen is either free from, or contains but a very small amount of, colouring matter. The reddish urine in granular disease of the kidneys furnishes less albumen by heat than the straw-coloured. Nitric acid and a mixture of one part of nitric and three of hydrochloric acids are more delicate tests of the presence of albumen than heat. Several sources of fallacy have been pointed out by writers which should not be overlooked when resorting to these tests. 1st. Heat will produce a white precipitate in urine containing an excess of earthy phosphates, but this will disappear on adding a drop of nitric acid, and distinguish it from albumen. 2d. Nitric acid will produce white deposits in patients taking copaiba, cubebs, or other resinous substances; but heat has no such effect. 3d. Nitric acid will, in some instances, produce a buff-coloured amorphous deposit in the high-coloured urine in fever, but heat does not cause this change. 4th. Albumen combined with alkalies does not coagulate by heat; therefore nitric acid should be used if the urine be alkaline. 5th. Albumen in an incipient state may not be detected by heat, but readily by means of the acids.

101. Albumen is sometimes found in the urine in a coagulated state, presenting a tubular vermicular appearance, being casts of the uriniferous tubules of the kidneys, often with portions of epithelium adhering to them; and, according to Dr. G. JOHNSON, loaded with fatty globules. These casts, when recently passed, appear like large hairs, but form after a time a dirty-white sediment, which a solution of potash gelatinizes, and distinguishes from mucus. This deposit is pathognomonic of the changes which terminate in granular disorganization of the kidneys.

102. *Blood* passed in considerable quantity in the urine may either be more or less intimately mixed in the urine, or it may have coagulated in blackish masses like pieces of black currant-jelly, linear masses like leeches being passed through the urethra with great suffering. In the former case the blood generally is poured out in the kidneys or their pelvis; in the latter it is most frequently effused in the bladder. In either case the urine is always more or less coloured, often so deeply as to present a Port-wine colour; the microscope showing some entire blood-globules,

and others with their investing membrane broken down, and their coloured contents diffused in the urine. If the quantity of urine be small, the urine may appear like the washings of meat, or of a dirty or dingy hue, the red globules being still recognisable by the microscope. The coagulation of the urine by repose seldom occurs: it is owing to the presence of fibrin, which, however, is very rarely effused without an admixture of blood-globules, giving the coagulum a reddish colour, or of a fatty matter, imparting to it a whitish or opaline hue.

103. *Hæmatosin*, or the colouring matter contained within the sacs of the blood-globules, imparts to the urine a deepness of tint in proportion to the quantity of the colouring matter which has escaped from the sacs of the blood-globules, or rather to the number of these globules which are ruptured. Generally, however, the urine, when recently voided, contains some globules that remain entire; and, with the colouring matter, more or less albumen, which is affected, as shown above, by heat and nitric acid, excepting that the coagula are more or less brown, owing to the presence of hæmatosin. When, however, the urine is much loaded with *purpurine*, or *uric acid*, or with *bile*, these may be mistaken for hæmatosin. The *first* of these will not be affected in colour or transparency by a boiling heat; the *second* is not affected by heat, and is at once distinguished by the characters of the deposit; the *third* may be detected by pouring a thin layer of the urine on a white plate or sheet of writing paper, and letting a drop or two of nitric acid fall upon it, when a change of colours, in which green and pink predominate, will be produced. *Hæmatozylon*, *parceira*, *chimaphila*, and *senna*, the former especially, will impart a reddish or brownish hue to the urine; but these will be distinguished from hæmatosin by the knowledge of their having been taken, by the black precipitate produced by sulphate of iron when the first of these has produced the redness; and by the absence of albumen and hæmatosin as regards all of them.

104. The presence of blood-globules in the urine is best determined by the microscope. If the blood be recently effused, they will either be found adhering in rouleaux, or unaltered in figure. But if it have been effused for some time, or if the effusion has been slow, or the exudation of an asthenic character, the linear arrangement of the globules is lost, the investing membrane, being ruptured, is collapsed around their corpuscles or nuclei, and ultimately the globules appear irregular in their margins.

105. (b) *The pathological indications* of the presence of the elements of blood, or of blood in any form, in the urine, has always been of importance; but it has become of even greater importance to the physician since the enlightened investigation by Dr. BRIGHT of the diseases of the kidneys. When pure blood, or even the admixture of its globules in large quantity, is observed in the urine, it may be presumed that active or passive hæmorrhage from some part of the urinary passages has occurred; the more pure the blood, and the less intimately mixed with the urine, the more probable is the effusion to have taken place in the lower passages of the apparatus. If the quantity of hæmatosin be so small as only to tint the urine, it is to be presumed that both it and the albumen also present result from the congested state of the kidneys connected with

the cachectic inflammation of these organs, which terminates in the organic changes which render them incapable of eliminating the nitrogenized elements of urine and of depurating the blood, although the secreting power is so far preserved as to separate the albumen and water, this latter element being ultimately very incompletely removed. (See *art. KIDNEYS*, § 83, *et seq.*)

106. When the presence of albumen in the urine was first shown to be a proof of granular disease of the kidneys, I contended (see *art. Dropsy*, § 36, *et seq.*) that this state of urine existed in several other diseases, especially in the febrile and exanthematous maladies of children, and when congestion of the kidneys is occasioned by other affections or circumstances, although not always or continuously observed, that yet it was a contingent and occasional or temporary occurrence. Since this statement was made, from a varied observation, the truth of it has been confirmed by many subsequent observers. When blood is voided in large quantity, or when coagula are passed with the urine, breach of surface or lesion of a blood-vessel may be inferred; but the particular cause of lesion, whether congestion, rupture of a vessel, or injury, or irritation of a calculus, or malignant or fungoid disease, and the seat of either of these morbid conditions can be ascertained only from a careful examination of existing symptoms, in connexion with the changes in the urine just mentioned (§ 105, 106), and with the circumstances attending the retention and calls to void this excretion.

107 (c) *Therapeutical Intentions*.—These are varied, or even opposite, according to the conclusions at which the physician will arrive after due examination and consideration of the peculiarities of each case, respecting the seat, cause, and vital conditions of hæmaturia, as fully set forth under this head in the *article HÆMORRHAGE*. (See *Hæmorrhage from the Urinary Organs*, § 204-220.)

108 *B PURULENT MATTER IN THE URINE*.—Pus is seen in the urine consequent upon suppuration in the kidneys, or in any part of the urinary organs, or in parts communicating with the urinary apparatus. It is also contended that, in cases of abscess of internal viscera, the purulent collection is sometimes absorbed and discharged with the urine. But it is more probable that pus-globules, when absorbed, are metamorphosed, either during their passage into or during their circulation in the blood, and that they cannot be eliminated by secreting organs unless thus metamorphosed or reduced to simpler elements.

109. a. *The appearances of purulent urine* vary with the seat of the disease. This urine is generally acid or neutral. The pus falls to the bottom of the vessel by repose, and forms a dense homogeneous deposit, of a pale greenish or cream colour. It never liangs in a stringy form in the urine like mucus, unless the urine be alkaline, and it becomes uniformly diffused in the urine by agitation. If the deposited pus be agitated with an equal quantity of liquor potassæ, a dense translucent gelatinous mass, of a thick mucous appearance, is formed. When the pus is agitated with ether, fat is dissolved, and left in the form of butter-like globules, when the ether is allowed to evaporate. The urine decanted from the purulent deposit yields albumen on the application of heat or nitric acid. When purulent

urine is alkaline, the deposit is viscid, and is not readily diffused by agitation through the fluid, resembling some mucous deposits. The presence of albumen in the purulent urine, "and the conversion of the deposit into a white granular mass, destitute of its previous viscosity, by the addition of acetic acid," indicate the nature of the deposit. In females, the urine may contain a purulent matter derived from the vagina, in cases of leucorrhœa—a circumstance requiring consideration.

110. *b. Microscopic Characters.*—Pus consists of round globules, somewhat larger than blood-globules, floating in an albuminous fluid, or *liquor puris*, which differs from the *liquor sanguinis* chiefly in the absence of fibrin, and consequently in the inability of coagulating spontaneously. Under the microscope, the globules appear "white, roughly granular exteriorly, and are much more opaque than blood-globules. On the addition of a drop of acetic acid, the interior of the globule becomes visible, and is found to be filled with several transparent bodies or nuclei." Hence the pus-globule is a regularly organized body, consisting of a granular membrane enveloping transparent nuclei, being, in other words, a nucleated cell. (*See DISEASE*, § 131, 132, and the *Microscopic Characters* more fully in the *art. Pus*, and in *URINARY BLADDER*, § 48.)

111. *C. Mucus* is present in healthy urine in very small quantity. When irritation exists in any part of the urinary apparatus the mucus is greatly increased, and generally in proportion to the amount and extent of it, this secretion varying from a flocculent cloud in the urine to the production of a fluid so viscid as to form a copious ropy deposit. This condition of the urine is generally alkaline, and undergoes a putrefactive change soon after it is passed, or even before being voided if it be long retained. Although it be acid when passed, it rapidly becomes ammoniacal. Mucus contains no albumen admitting of coagulation by heat or nitric acid (§ 100), and hence mucous urine simply "can never be albuminous like pus, unless the albumen be derived from some other source. Agitated with ether, mucus gives merely traces of fat, and in this respect also differs from pus." (*For the pathological and therapeutical relations of Mucous Urine*, see the *art. URINARY BLADDER*, § 47, *et pluries*.)

112. *D. Epithelium.*—Exfoliation of the epithelial covering of the genito-urinary mucous surface is constantly taking place, but with very different rates of rapidity. This covering is sometimes partially detached, so as to appear like patches of membrane-like mucus; some of the epithelial cells being irregularly lacerated, others entire, and readily recognised by the aid of the microscope. When distended by fluid they are oval cells, which become irregularly angular and flattened when partially empty. When quite empty they present in each a central nucleus projecting above the surrounding surface. These cells are said sometimes to contain fat-globules, especially in the *Morbus Brightii*. When the exfoliation of epithelium is copious, a deposit is thereby formed in the urine, resembling mucus, but differing from it in the absence of viscosity. With *liquor potassæ* this deposit gelatinizes nearly as perfectly as when pus is present. When an abundance of epithelium is found in the urine, oxalate of lime often also is present; the irritation of the mucous surface of the urinary pas-

sages, especially in the kidneys, very probably at the same time that it detaches the epithelium, converts the uric acid and urates into the oxalate.

113. *E. SPERMATOZOA*, or what has been called spermatic animalcules, are sometimes found in urinary deposits, when the urine of the male adult has been allowed to repose for a time.—*a.* The only means of distinctly determining the presence of semen in the urine is by ascertaining the existence of spermatozoa by the aid of the microscope. "These minute bodies never occur living in urine, unless protected by the presence of a deposit of pus, in which they retain their power of moving a long time after emission." In the microscope, "the spermatozoa will be observed as minute ovate bodies, provided with a delicate bristle-like tail, which becomes more distinct on allowing a drop of urine to dry on the glass. Mixed with these are generally found round granular bodies, rather larger than the body of a spermatozoon, and nearly opaque from the numerous asperities on the surface of the investing membrane. These appear to be identical with the seminal granules described by WAGNER and others" (*Op. cit.*, p. 359.)

114. *b.* The presence of spermatozoa in the urine furnishes certain *pathological indications* of much importance. They may be present owing to the discharge of urine immediately or soon after seminal emission, the urine washing away the portion of semen which may remain in the urethra; or owing to a costive motion having pressed upon the spermatic receptacles, so as to press out a portion of their contents. However the presence of these bodies in the urine may be accounted for, the fact that they are commonly observed in persons who have weakened their sexual organs, either by excessive female intercourse, or by the unnatural vice of masturbation, is indisputable; and in such persons chiefly or only spermatozoa, and the much-discussed affection of spermatorrhœa, is observed. The pathological and therapeutical indications furnished by this condition of the urine are considered under the head of *IMPOTENCE*, and more fully under that of *POLLUTION, voluntary and involuntary*.

115. *F. FATTY OR OILY MATTER* has not unfrequently been found in the urine, generally, however, in minute traces only, and very rarely in any considerable quantity. It is most probable that some of the instances in which oil has been said to have existed in the urine have been those in which the oil-like pellicles of the earthy phosphates have formed on the surface of the urine. The genuine states of fatty urine have generally resembled milk in colour and opacity, and have gelatinized on cooling. The term chylous urine has been applied to these states by Dr. PROUT. Dr. EICHHOLZ and Dr. G. JOHNSON contended that oil or fat existed in the urine in granular disease of the kidneys, owing to the superabundance of fat in the epithelial cells of the tubular structure of the kidneys, and to the escape of these cells from the tubuli and admixture with the urine. But the quantity of fatty matter thus mingled with the urine is rarely such as to give rise to appearances indicative of its existence, unless the deposit be examined under the microscope, when the cells containing oil, sometimes presenting casts of the tubes from which they have been detached, may be observed.

116. In most cases of chylous urine, albumen is present in very varying quantity, and forms

with the fat an intimate admixture or emulsion. The fat may be obtained by agitating the urine with an equal quantity of ether in a tube. The presence of fat in albuminous urine may be viewed as a strong indication of organic disease of the kidneys; but the combination rarely exists in such a manner as to give rise to the chylous appearance of the urine. It should not be overlooked that instances sometimes occur in which hysterical females, to create interest in their cases, or to obtain other ends, have imparted a morbid appearance to their urine, by adding to it milk, or small quantities of blood or other matters, by which the medical attendant has been deceived. Such instances have come before me and other physicians with whom I am acquainted. I have rarely seen cases of chylous urine. The most remarkable instance of it which I have observed was in a mulatto young man from the West Indies. Dr. G. BIRD states that, in the chylous urine he has examined, he has failed in detecting under the microscope the slightest appearance of oil-globules, blood-disks, or pus-granules; the opacity appearing to depend upon the presence of particles so minute as to present no defined form. M. L'HERITIER has, however, remarked that oily globules can always be detected in fatty urine; and Dr. SIMON, of Berlin, has made the same remark, and has stated that he has met with three varieties of fatty urine: one in which the fat is merely diffused through it, and collects on its surface by repose, as in cases recorded by Dr. ELLIOTSON; the other in which the fat is combined with albumen; and a third, in which the fatty matter existed with casein as an emulsion, forming the true milky or chylous urine. Dr. BENGE JONES has investigated this state of the urine, and has arrived at the following conclusions respecting it:

1st. The fat on which the milky aspect of the urine depends appears after the absorption of chyle, but the albumen, fibrin, blood, and alkaline salts may be found even when no food has been taken, and consequently no chyle formed. 2d. During absolute rest, albumen disappears from the urine, and does not reappear in any quantity, even after taking food, unless active exercise is employed. A short time before rising early, the urine gelatinizes by repose, but is free from fat. 3d. This state of urine does not depend upon the presence of an excess of fat in the blood, as proved by actual analysis. 4th. The seat of this disease is probably some slight alteration in the structure of the kidneys, by which, when the circulation through these organs is most active, one or more of the constituents of the blood exude from the capillaries and escape into the urine.

Dr. G. R. BOUYUN, of Demerara (Dr. G. BIRD states), has observed cases of chylous urine so frequent in creoles and negroes as to be often epidemic in that country. This state of the urine appears to be attended by irritative fever and emaciation, as in diabetes. He attributes the disease to lesion of the assimilative functions; and he treats it by the free administration of a decoction of the mangrove bark (*Rhizophora racemosa*). This medicine acts freely on the skin, increases the secretion and alters the character of the urine, and improves the general health.\*

\* *Kiesteine*.—In 1831, NAUCHÉ, of Paris, described a peculiar gelatino-albuminous ingredient, found, as he supposed, only in the urine of pregnancy. When the urine of a pregnant female was allowed to stand in a

117. *G. CONFEROID GROWTHS*.—*Torula Cerevisia*—*Fungoid Growths*—*Vibrios*, &c., have been described as existing in the urine, in certain states of the frame, chiefly characterized by remarkable depression of vital power. The existence of these may be imputed to the presence of albuminous, fibrinous, saccharine, or other matters in the urine, and to changes which have taken place in these after the urine has been discharged, although they may possibly be formed in the bladder, when the urine is long retained in these morbid states in this viscous, especially when the vital energies are very much depressed, and the other circumstances favourable to these productions, already adverted to (§ 82), are present.

118. *H. HYDATIDS* have been passed in the urine; but cases in which they thus have been observed are extremely rare. Instances have, however, been recorded in the Philosophical Transactions (No. 273), and in the Medical Observations and Inquiries by Mr. RUSSEL (vol. iii.). A case came before me many years ago, in which a number, varying in size from a small pea to that of a large bean, were passed in the course of two or three days. Soon afterward the case passed from under my observation, without being able to ascertain its issue.

119. xii. *FOREIGN BODIES*.—*Worms*, &c., have been often found in the urine, in some cases in consequence of having been introduced into the bladder, in others from having been put into the urine with the intention of deception; and in more instances owing to their passage by ulceration, penetration, or otherwise, through the parietes of some portion of the digestive canal, or

glass vessel, a cotton-like, cloudy deposit first appeared, afterward oblong points or specks, which, increasing in number and agglomerating, covered the surface of the fluid and the sides of the vessel, in the form of a firm, tenebrous pellicle. EQUISIER followed, sustaining the same positions. In 1840, Dr. G. BIRD published the results of his observations on the urine of thirty pregnant females, and came to the conclusion that the pellicle noticed by NAUCHÉ was composed of the triple phosphates, with some granular and oily matter; and though furnishing a strong corroborative test of pregnancy, is not, however, an entirely reliable one. Our distinguished countryman, the late ELISHA H. KANE, in his inaugural dissertation (*Am. Journ. of Med. Science*, N. S., vol. iv., 1842), from a great number of experiments and observations, came to the following conclusions:

"1st. That the *kiesteine* is not peculiar to pregnancy, but may occur whenever the lacteal elements are secreted without a free discharge at the mammae.

"2d. That though sometimes obscurely developed, and occasionally simulated by other pellicles, it is generally distinguishable from all others.

"3d. That where pregnancy is possible, the exhibition of a clearly-defined *kiesteine* pellicle is one of the least equivocal proofs of that condition; and,

"4th. That when this pellicle is not found in the more advanced stages of supposed pregnancy, the probabilities, if the female be otherwise healthy, are as 20 to 1 (\$1 to 4), that the prognosis is incorrect."

More recently, Dr. G. T. ELLIOT, Jun., of New York (*N. Y. Journal of Med.*, Sept., 1853), has published the results of his experiments on the urine of 160 pregnant females, and concludes that there are no recognisable peculiarities in the urine of pregnancy, that there is nothing positive in the indications furnished by *kiesteine*, and that its appearances can scarcely ever be called "corroborative" of pregnancy (*Loc. cit.*, p. 181). On the whole, the opinion of LEHMANN seems most probable, viz., that "*kiesteine* is nothing else but the formation of crystals of triple phosphate, and fungoid and confervoid growths, which take place when the urine becomes alkaline" (*Phys. Chemistry*, Philad., 1856). According to Professor DRAPER, *kiesteine* is composed of casein, butyric fat, and the phosphate of magnesia, and is a normal ingredient in the blood, especially of pregnancy, being generated from its albumenoid compounds at the rate of about 30 grs. per hour (*Human Phys.*, N. Y., 1856, p. 231.)

abdominal parietes. Whoever may be desirous of perusing cases of this description will find a number of them related in the *Ephemerides of Natural Curiosities*, and in the *Memoirs of the French Academies*, and various other works enumerated by PLOUQUET and REUSS.

120. IV. GRAVEL.—*Urinary deposits*, such as are above described, are formed on the cooling of urine, and are, as described, either loose and pulverulent, or more concrete, crystalline, or sand-like. These deposits, although associated with, or symptomatic of, various diseases, may occasion, as respects their effects upon the urinary organs, but little disorder. But when deposits are formed in the warm urine within the urinary apparatus, owing either to the quantity of these matters contained in the urine, or to changes in the states of their constituents, or of temperature, vital endowment, &c., and are discharged with the urine in the form of a fine powder, or of crystalline, sand-like particles, or of small masses, then the disease is termed *gravel*, and the symptoms are sometimes very severe.

121. The discharge of such gritty matters as these with the urine is usually attended by symptoms of irritation, and pain in the region of the kidneys, ureters, bladder, and in the urethra, thereby constituting while characterizing the complaint commonly denominated gravel. The signs of irritation may be slight, or they may be severe in one or other of the situations just named, or even in two or more of them. But the signs, as well as the causes which produce this condition of the urine, are the same as those which attend the formation of calculi in the urinary apparatus, although they are very frequently much less severe. The chemical constitution of the gravel discharged is generally the same as that of urinary calculi; the difference consisting chiefly in the constituents precipitated from the urine being detached or incoherent, or forming numerous minute crystals, instead of large concretions, of many concentric layers. In the former case, the deposits within the urinary organs are washed away by the urine before they have been sufficiently long retained to concrete into a nucleus, or to become a large calculus—or to assume the characters now to be described.—CALCULI. The *treatment of gravel* is manifestly the same as that recommended for urinary deposits and *urinary calculi*. (See § 179, *et seq.*)

122. V. URINARY CONCRETIONS OR CALCULI.—Correct views as to the composition and formation of urinary concretions or calculi are of comparatively recent date. Previously to VAN HELMONT these concretions were believed to be derived from matters contained in the food and drink; but he contended that they are not formed from these sources. HALES confirmed the opinions of VAN HELMONT as to the differences between urinary concretions and common stones, and first directed attention to the discovery of a solvent for these concretions. BOYLE, WHYTT, ALSTON, SLARE, and others, subsequently speculated on the subject of solvents for calculi. WHYTT proposed lime-water for this purpose; and ALSTON contended that, although lime-water is of some service in urinary affections, it is not a solvent of calculi. At the commencement of the last century the Leyden School of Medicine taught more correct doctrines of the formation of urinary concretions than had previously been entertained, and showed that these nuclei were de-

rived from the kidneys or from the bladder. VAN SWIETEN contended that the elements of calculi exist in the urine of men the most healthy, and that if the urine be evacuated before these elements concur in the formation of a concretion, no such production takes place. He considered that the concurrence of the elements in the formation of calculi is exerted more or less slowly in different persons; and that according to the rapidity or slowness of such formation, the concretions are formed either in the kidneys or in the bladder. In 1776 SCHEELÉ discovered uric acid, and found it in all the calculi he examined, as well as in all the urine. BERGMANN soon afterward discovered lime in certain concretions. In 1797 WOLLASTON published his discovery of three calculi in addition to those described by SCHEELÉ—viz, the fusible, mulberry, and the bone-earth—and demonstrated the chemical composition of these calculi. A few years afterward, FOURCROY and VAUQUELIN announced the presence of urate of ammonia and silica in urinary concretions. Dr. WOLLASTON, in 1810, discovered cystic oxide as an urinary calculus. Dr. MARCET published an able work on urinary concretions in 1817; and Dr PROUT furnished, in 1821, more extended and exact views as to their formation in his treatise on this subject. Since this period the works of Mr. WILSON, of Sir B. C. BRODIE, of Mr. CROSSE, of Norwich, of Dr. T. THOMSON, of Dr. CUMIN, of Dr. OWEN REES, of Dr. BENCE JONES, of Mr. COULSON, and the more recent publications of Dr. PROUT, have carried the pathology and treatment of urinary concretions to their present very high position in practical medicine and surgery.

123. A. The *form of urinary concretions* is generally more or less globular or ovoid, especially after remaining long in the bladder. Renal calculi are, however, often of an irregular form, owing to their being moulded in the pelvis of the kidney, &c., or are branched like a coralline. Sometimes those found in the ureter are cylindrical. When two or more calculi exist in the bladder they often present a polyhedral or an irregular shape, from one or more of their sides being flattened, either by attrition or by diminished concentric deposition on these sides. When the calculi formed in the kidneys and passed into the bladder are irregular or branched, the shape of the nuclei which they constitute is not altogether removed by the successive deposits formed around them in the bladder. When a portion of a calculus is embraced by a fold of the mucous membrane, or sacculated between the muscular fasciculi or coats of the bladder, the part exposed to the urine increases by successive deposits, so that the sacculated portion ultimately appears to form a pedicle to the entire calculus. (COULSON.)

124. B. The *size and weight of urinary concretions* are most various—ranging from a few grains to many ounces. EARLE mentions one weighing forty-four ounces; LISTER, one of fifty-one ounces; and MORAND, one weighing six pounds three ounces! The concretion described by EARLE measured sixteen inches in circumference. The *number of calculi coexisting in the bladder or in the kidneys* is often very various. Most frequently vesical calculi are solitary; but two or even more are not uncommon. They are often numerous in one or both kidneys, but generally not equally so in both. From ten to twenty or even thirty in both are not uncommon. An

equally great number are very rarely found in the bladder, although it is stated that fifty-nine small calculi were found in the bladder of BUFFON.

125. *C* The *surface* of calculi also varies in its colour and characters. The colour passes from "white through pale yellow to brown, brownish-green, and even almost to black. Phosphatic calculi are often white; those of uric acid vary from yellow to brown; those of xanthic oxide have a cinnamon brown tint; while calculi of oxalate of lime vary from yellow to yellowish-brown, brownish-green, or even blackish-green." The surface is either smooth, and even polished, or covered with minute crystals, or more or less rough, and even tuberculated, as in the mulberry calculus.

126. *D*. The *internal structure* or section of a calculus is either uniform, or formed of concentric layers surrounding the nucleus; and, in addition to the concentric lines indicating the separation of the layers, other lines, radiating from the nucleus to the periphery, are observed in many of the concretions. In some the concentric layers are easily separable, in others very firmly adherent, especially when the layers are indicated only by very faint lines, as in the oxalate of lime calculus.

127. *E*. The *chemical composition* of the nu-

cleus, and of the concentric layers or deposits, may be the same; or that of the superimposed strata may differ from the nucleus, or each of the strata may be different. The *constituents* are, *first*, those which form entire calculi or layers, in a nearly pure state, and, *secondly*, those which contain, associated with these constituents, small quantities of other substances.

128. *First Class*.—1. Uric acid. 2. Uric or xanthic oxide. 3. Urates of ammonia. 4. Cystic oxide, or cystine. 5. Ammoniaco-magnesian phosphate. 6. Oxalate of lime. 7. Phosphate of lime. 8. Carbonate of lime. 9. Mixed phosphate of lime, and phosphate of magnesia and ammonia.

129. *Second Class*.—Those concretions which, with the foregoing, contain the following in small quantities: 1. Urates of potass. 2. Urates of soda. 3. Urates of lime. 4. Urates of magnesia. 5. Carbonate of magnesia. 6. Silica. 7. Organic matter, fat, extractive, albumen, vesical mucus, blood. In addition to these, oxide of iron, benzoate of ammonia, phosphate of iron, urea, oxalate of ammonia, hydrochlorate of ammonia, in very minute quantities, are said to have been formed.

130. The following TABLE, drawn up by Dr. BENCE JONES, shows the readiest means of ascertaining the composition of urinary calculi:

1. By Heat.	2. By Acids.	3. By Alkalies.	Nature of Calculus.	Additional Tests.
Destroyed by heat.	With nitric acid, red.	Soluble in carbonate of potash, evolving ammonia. Soluble in carbonate of potash, evolving no ammonia.	Urates of ammonia. Uric acid.	Soluble in water when boiled. Not soluble in water when boiled.
	With nitric acid, not red.	In ammonia, soluble, crystallizing when evaporated.	Cystic oxide.	Soluble in strong caustic potash; the solution gives sulphuret of lead when boiled with a solution of acetate of lead.
Not destroyed by heat.		In ammonia, soluble, not crystallizing when evaporated.	Uric or xanthic acid.	Dissolves without effervescence in nitric acid, leaving a lemon-coloured residue, soluble in strong sulphuric acid, not precipitated by dilution.
	With hydrochloric acid, soluble; before heat effervesces.	In ammonia with difficulty soluble, not crystallizing.	Fibrin.	With nitric acid becomes yellow.
	With hydrochloric acid, soluble; after heat effervesces.	Solution in acid, when neutralized, gives a white precipitate with carbonated alkalies and oxalate of ammonia.	Carbonate of lime.	Soluble in dilute acetic acid, with effervescence.
		Solution in acid, when neutralized, gives a white precipitate with carbonated alkalies and oxalate of ammonia.	Oxalate of lime.	Insoluble in acetic acid. Decomposed by strong sulphuric acid, yielding carbonic acid and carbonic oxide.
	With hydrochloric acid, soluble, without effervescence, or before or after heat.	Solution in acid, with excess of ammonia, gives a white crystalline precipitate. Solution in acid, with excess of ammonia, gives an amorphous white precipitate. Solution in acid, with excess of ammonia, gives a white, partly crystalline, partly amorphous precipitate.	Phosphate of ammonia and magnesia. Phosphate of lime. Mixed phosphates.	With phosphate of lime is very fusible before the blow-pipe. With phosphate of magnesia and ammonia is very fusible before the blow-pipe. Easily fusible, without addition, before the blow-pipe.

131. *i. Uric Acid Calculus*.—Uric acid is the most frequent constituent of urinary concretions, either alone or in combination with bases, especially urates of ammonia, &c. Calculi consisting of uric acid only, or containing in addition a small quantity of colouring matter, are more common than those of any other single constituent. Mr. COULSON states the relative number of pure uric acid calculi in the Museum of the College of Surgeons to be one third of the whole collection. Dr. PROUT estimated the general average of this concretion in the several known collections to be nearly 1:6½. The relative proportions of those

composed chiefly of uric acid mixed with urates of ammonia, and of urates of ammonia with minute proportions of urate and oxalate of lime and phosphates, are estimated at 1:3½; and including the calculi in which the nuclei are formed of uric acid, the proportion is about 1:1½. The calculi into which uric acid enters in larger or smaller proportions, as one of the constituents, in the Collection of the London College of Surgeons, are as 1 to 1:36 of the whole number. Two chief varieties of this calculus consist—1st, of that in which the uric acid is deposited in more or less distinct concentric layers, the section of the calculus pre-

senting a series of concentric circles of a compact and semi-crystalline structure; 2d, of that in which the acid forms a mass of crystalline amorphous grains. These varieties, however, often are mixed, or pass into each other. The first of these have a somewhat granular or finely tuberculated, but smooth or polished surface. When broken, the fragments are angular, whose surfaces are fibrous, as if the concretion were composed of crystalline fibres radiating from the centre to the circumference. The fracture is always in the direction of these radiating fibres and of the concentric layers. The second variety, in which no concentric lamellæ are seen, consists either of a firm aggregation of crystalline grains presenting a radiated appearance, or of a porous and earthy structure, often more or less loosely cohering. These calculi are less regular than the former, "have a rough surface, a granular and unsymmetrical fracture, and are most frequent in the kidneys. The nucleus of the laminated variety frequently presents this character. This form of calculus is more liable than the compact laminated variety to spontaneous fracture in the bladder." Calculi sometimes present cracks in the direction of the radiating fibres, probably owing to an unequal density in the deposits.\*

[\* CHARACTERISTICS AND TESTS OF URINARY DEPOSITS.

I. Coloured.

(A.) *Crystalline*, which is *uric acid*, rhombic form, or square tables, soluble in nitric acid by heat in effervescence; on evaporation, leaves a beautiful pink deposit (*muroid of Liebig*), becoming purple on the addition of ammonia; soluble in a boiling solution of potash, from which hydrochloric acid precipitates it as a white, gelatinous substance, speedily becoming crystalline. Before the blow-pipe blackens and dissipates with a peculiar animal odour.

(B.) *Amorphous*, which may be,

I. *Pink, red, or yellow Urate of Ammonia*; is soluble in hot water, and again deposited on cooling; soluble in boiling solution of carbonate of potassa; boiled with solution of potassa, evolves ammonia; has all the characters of uric acid with nitric acid. Before the blow-pipe comporting itself as uric acid, except that it gives out ammonia and decrepitates strongly.

II. *Red or brown Blood*.—Urine becomes opaque by heat or nitric acid; microscope detects the blood disks, which often subside, and form a distinct layer at the bottom of the vessel. Chloride of sodium and other neutral salts heighten the colour.

III. *Green or brown Bile*.—If from the brown colouring matter (biliphoen), on addition of nitric acid, the urine becomes blue, then green, afterward violet and red, and lastly assumes a yellow or yellowish-brown colour; if in small quantity, the intermediate colours are not observed; hydrochloric acid changes the urine to green. If from *bilin*, this may be detected by *Pettinkofer's test*, as follows: (Add to the urine, by drops, two thirds of its volume of sulphuric acid, keeping the mixture below 144°; add a few drops of a solution of cane-sugar (1 to 5 of water), and shake the mixture, when, if *bilin* be present, a violet-red colour will be developed.)

II. Colourless.

(A.) *Crystalline*, which may be,

I. *Oxalate of Lime*.—Octahedral or quadrilateral crystals, insoluble in acetic acid; soluble in nitric and hydrochloric acids; boiling with carbonate of potash forms soluble oxalate of potash and insoluble carbonate of lime. The former gives characteristic reactions with chloride of calcium, sulphate of copper, and nitrate of silver; before blow-pipe becomes carbonate of lime. On continuing the heat, lime only is left, giving out heat on the addition of water, and browning turmeric paper.

II. *Phosphate of Ammonia and Magnesia* (triple phosphate).—Right rectangular, or trilateral crystals, soluble in diluted mineral and acetic acids, from which, by an addition of ammonia, precipitated in a crystalline form; soluble in boiling solution of potassa, with evolution of ammonia. Before the blow-pipe gives off ammonia, and runs into a white enamel; addition of phosphate of lime imparts ready fusibility.

III. *Cystine*, in simple or compound tables, insoluble in boiling water, soluble in ammonia (with odour of sweet-briar) and alkalies, and precipitated by acetic acid;

132. A third variety of uric acid calculus is known as the pisiform, and is very common. It is seldom solitary; many may exist at the same time in the bladder, and some may be voided by the urethra. They are chiefly formed in the kidneys, and are rarely larger than a common bean or large pea. They have irregular angular shapes caused by attrition against each other, are crystalline, laminated near the surface, and often coated with a thin layer of urate of ammonia.

133. The specific gravity of uric acid calculus varies with the density, and is usually from 1.5 to 1.786; but it has been observed in rare instances as low as 1.276. The colour of this calculus varies from pure white to a deep brownish-red, the colouring matter being of the same nature as that of the urine. (§ 18.) Uric acid is insoluble in alcohol and ether, but is soluble in solutions of potash and soda when heated, and in phosphate and bichlorate of soda, and is precipitated from these by acids. Solutions of the alkaline bicarbonates do not dissolve it. Nitric acid dissolves and decomposes it, equal volumes of carbonic acid and nitrogen being evolved. "Sulphuric and hydrochloric acids do not affect it. Uric acid is a feeble acid, but combines with bases, and forms salts with them. The alkaline urates are sparingly soluble, but very much more so than the pure acid."

134. ii. *Urate of ammonia calculus*, unmixed, is rare. In the collection of the College of Surgeons it exists in the proportion only of one in 500, although this substance forms the nucleus of nearly one third of the whole collection.—(Coulson.) Dr. Prover, in 1823, first fully demonstrated the nature of this concretion, which seldom exceeds an inch in diameter, and is almost peculiar to childhood. It very rarely occurs in an unmixed state after puberty, and its formation is attended by much constitutional irritation. It is flattened, ovoid, smooth, of a brownish-grey or clay colour, often with a greenish tinge. It is usually compact in structure, earthy and brittle, consisting of thin concentric layers, so closely applied to each other as to appear homogeneous. The laminae are, however, easily separated. Urate of ammonia is a common deposit from urine, having an alkaline reaction, carrying with it more or less colouring matter, which gives it a yellow or brown hue. In its pure state it is white, and much more soluble in water than uric acid.

135. This salt is often associated with oxalate of lime in calculi, the formation of this latter being preceded by a condition of the urine which favours the deposit of urate of ammonia, so that the nucleus may be formed of urate of ammonia, while the surrounding layers are a mixture of these salts. These calculi sometimes also con-

insoluble in alcohol, tartaric and oxalic acids, and bichlorate of ammonia.

(B.) *Amorphous*, may be,

I. *Phosphate of Lime*, readily soluble in dilute hydrochloric and nitric acids, sparingly in acetic; precipitated by ammonia in an amorphous condition, forming, when collected on a filter, a horny mass; oxalate of ammonia in these solutions gives a white precipitate. Before the blow-pipe, first black, then white, leaving an ash which is neutral.

II. *Urate of Ammonia*.—Characters as above. (Coloured B.)

*Pus*.—The microscope detects pus globules. The urine coagulates more or less by heat; soluble in a solution of potassa, forming a tenacious, glairy fluid.

*Mucus*.—Insoluble in potassa; imparts little or no albumen to the urine; therefore slight or no coagulability by heat, &c.]

tain a small quantity of urate of lime. Urate of ammonia is also frequently associated with the earthy phosphates, either as a nucleus or in alternate layers, or mixed in various proportions with the other constituents.

136. iii. *Xanthic or uric oxide calculus* is so very rare as hardly to deserve notice, only four specimens of it having been found. It may be distinguished by the means stated in the Table given above (§ 130).

137. iv. *Cystic oxide calculus* is also rare. It is a product of the kidneys only, and hence should be differently named. Dr. PROUT found it only in four out of seven museums. That of the College of Surgeons contains one or two specimens. It is small, round, and yellowish, with a smooth semi-transparent and glistening surface. This substance is generally free from admixture with others; "but uric acid sometimes forms the nucleus, and a layer of uric acid has been found surrounding a nucleus of cystic oxide. It is also occasionally associated with ammoniaco-magnesian phosphate and carbonate of magnesia."

138. v. *Oxalate of lime calculus*, in an unmixed state, exists in the Museum of the College of Surgeons in the proportion of 1:20; in that of Saint Bartholomew, as 1:15; and in that of Guy's Hospital, as 1:14½. When oxalate of lime calculi having nuclei of urate of ammonia are included, the proportion in the Museum of the College of Surgeons is 1 in 3½. If all the calculi be taken in which the oxalate of lime exists in any amount, then the proportion is, according to Dr. PROUT, in St. Bartholomew's Hospital, 1:4½; in Guy's, 1:4; in Norwich, 1:7½; in Manchester, 1:6½; in Bristol, 1:3½; in Swabia, 1:27; and in Copenhagen, 1:2½, the average proportion being 1:4½. Oxalate of lime calculus is rarely pure, being associated with urate of ammonia, uric acid, urate and carbonate of lime, colouring matter, and blood. This calculus, long known by the name of Mulberry Calculus from its tuberculated surface and its resemblance to that fruit, has usually a rounded shape, its surface being dark-brown, or nearly black. Its internal structure is compact and hard, imperfectly lamellated, the layers forming waving lines, the colour of which is such as to give the surface of its section a resemblance to a section of a piece of gnarled oak, varying from white or yellow to yellowish-brown, or dark brownish-green. The tubercles of the surface appear to consist of stellate crystals. A second variety of the oxalate of lime calculus is crystalline throughout, its surface being studded with crystals of the oxalate in acutely-angled octahedra, these being nearly pure oxalate of lime. A third variety consists of small rounded masses, with a smooth, polished surface, known as the hemp-seed calculi. It is occasionally crystalline at the centre and laminated toward the surface, but the laminae are so fine as to give the section almost a compact appearance. It is composed of mixed oxalate and phosphate of lime in variable proportions.

139. vi. *Phosphate of lime calculus* is rare, especially in a state of purity. Two varieties have been described, "one evidently of renal, the other of vesical origin. Although entire calculi of pure phosphate of lime are uncommon, this substance is often found nearly pure in the laminae of alternating calculi." Dr. PROUT states that calculi of phosphate of lime are in the ratio of 1:32½ in St. Bartholomew's Hospital; of 1:29 in Guy's;

of 1:132 in Norwich; and of 1:155 in the Bristol hospital. The general proportion of these calculi to others is 1:117. No specimen exists in the Museum of the College of Surgeons, and in some other collections. The calculi considered renal are composed of the neutral phosphate of lime; those considered vesical are more common than the former. Concretions of neutral phosphate of lime are usually pale-brown, with a polished surface, regularly laminated, and the laminae so slightly adherent as to be easily separable into concentric crusts. In some, radiating lines are seen perpendicular to the laminae. Those calculi contain animal matter which is precipitated from the alkaline urine with the phosphate of lime.

140. vii. *Ammoniaco-magnesian phosphate calculus* is commonly known as the "triple phosphate." This double salt rarely forms an entire calculus, but is a very common constituent of other calculi, either mixed with phosphate of lime, as in the fusible calculus, or forming layers in alternating calculi. The proportion of calculi consisting of pure phosphate of magnesia and ammonia, in the collection of St. Bartholomew, is as 1:129; in Guy's, as 1:43½; in the Bristol hospital, 1:218; in Copenhagen, 1:19½; in the Museum of the College of Surgeons, 1:200; while the other collections mentioned by Dr. PROUT contain no specimen. The general ratio is 1:126½. Ammoniaco-magnesian phosphate is a frequent deposit from alkaliescent urine, but usually mixed with more or less phosphate of lime. Calculi of this double salt "are generally white, uneven, and roughened by the projecting summits of the crystals, which are transparent in the recent state, but opaque and without lustre after being kept for some time. These calculi are either not laminated or imperfectly so, are friable and easily reduced to powder. But occasionally they are hard, compact, and laminated; exhibiting a semi-transparent crystalline fracture, which gives them the aspect of alabaster." (COULSON, *Op. cit.*, p. 291.)

141. viii. *Fusible Calculus*.—Calculi known by this name consist of a mixture of phosphate of magnesia and ammonia, with phosphate of lime in very variable proportions; and they form a considerable portion of all collections. In the College of Surgeons they are as 1:13½; in St. Bartholomew's as 1:12½; in Guy's, 1:3½; in Norwich, as 1:19; in Manchester, 1:8½; in Bristol, 1:12; in Swabia, 1:11½; and in Copenhagen, as 1:19½, according to PROUT, the average proportion being 1:12½. Fusible calculi are white, gray, or dull yellow, and more friable than any others, "being sometimes so soft as to whiten the fingers like chalk when handled: these are not laminated. Others have distinct lamellae, with sparkling crystals of triple phosphate between them, which are so slightly adherent as to be readily separated; others, again, are composed of crystals aggregated into a confused mass." These calculi are usually globular or ovoid, but sometimes very irregular in shape, being occasionally moulded by the cavity in which they are formed. "They often attain a large size, and sometimes fill the whole cavity of the bladder; in this case impressions of the folds of the mucous membrane are visible on the surface, and when two or more in the bladder, they take a cubic or tetrahedral form." Excrescences composed of triple phosphate are sometimes found, resembling pearls. The ammoniaco-magnesian

phosphate is most abundant in those which have a shining crystalline texture, the phosphate of lime in the earthy and amorphous variety. The fusible calculus is found in all parts of the urinary organs, and in large cysts, or in cavities in the prostate gland. According to Mr. TAYLOR, the earthy phosphates are rarely succeeded by any other deposit; the only exceptions being one in the College of Surgeons, in which layers of mixed phosphates exist in an oxalate of lime calculus, and one in St. Bartholomew's Hospital, in which a fusible calculus is surrounded by a layer of uric acid. The two ingredients of fusible calculi seem to have a distinct origin, the ammoniaco-magnesian phosphate being derived from the urine, while the phosphate, with a small proportion of carbonate of lime, is secreted together with mucus by the irritated mucous membrane. This is shown in calculi formed around a foreign body introduced into the bladder. This body is first incrustated with phosphate and carbonate of lime, derived, it is believed, chiefly from the mucous surface of the bladder; and subsequently, the irritation being extended to the kidneys, the urine becomes alkaline, and ammoniaco-magnesian phosphate is deposited, the layers near the nucleus containing more phosphate of lime than those near the surface of the calculus. As a secondary deposit the mixed phosphates are very common, few calculi remaining for a long period in the bladder without being incrustated by them. The uric acid calculus is least subject to this incrustation. These calculi commonly contain urate of ammonia and animal matter in considerable proportion, together with carbonate and urate of lime and uric acid.

142. ix. *Carbonate of lime calculus*, associated only with a little animal matter, is very rare in the human subject, but common in herbivorous animals, usually mixed in these with carbonate of magnesia. Carbonate of lime is, however, often found in variable proportion in the oxalate of lime and phosphatic calculi. BRUGNATELLI, PROUT, and SMITH have described the carbonate of lime calculi. They are always small, the largest not exceeding the size of a large almond; are white or gray, but sometimes yellow, brown, or reddish, and the surface is dusted over with a white powder. They show no concentric laminae, but irregular waved lines similar to those in the mulberry calculus. They are sometimes remarkably hard, and capable of receiving a high polish. Others passed by the urethra of a rounded and flattened form are compact, lamellar, and light brown. "No specimens of this calculus exist in the museums enumerated by Dr. PROUT, nor in that of the College of Surgeons." "Mr. SMITH describes eighteen removed from the bladder of a young man; and BRUGNATELLI forty-eight from a similar source, and sixteen, the size of a nut, from a woman."

143. x. *Alternating calculi* form a very large proportion of those formed in the human urinary apparatus. This alternation of the constituents in the layers of the same calculus is manifestly owing to successive changes in the urinary secretion, depending upon varying states of the constitution and vital and assimilative power. Alternating calculi consist of a series of alternating layers, differing in chemical composition. Some are composed of two layers, a nucleus of uric acid being covered by a deposit of urate of ammonia, or of oxalate of lime, or phosphate of lime,

or mixed phosphates. The nucleus may be oxalate of lime, followed by uric acid, or urate of ammonia, phosphate of lime, or mixed phosphates. "Other calculi have three differently-constituted layers; thus, a nucleus of uric acid may have deposits of oxalate of lime and mixed phosphates, or oxalate of lime and uric acid; or a nucleus of oxalate of lime, covered by uric acid and urate of ammonia; or a nucleus of mixed phosphates followed by phosphate of lime and mixed phosphates. Others, again, consist of four or even more layers: thus, a nucleus of uric acid incrustated by urate of ammonia, uric acid, and urate of ammonia; or oxalate of lime, followed by uric acid, oxalate of lime, phosphate of lime," &c. (*Op. cit.*, 296.)

144. The proportion of *alternating calculi*, of two layers differing in chemical constitution, appears from several sources to average 1 : 2½. The proportion of calculi consisting of three alternations are 1 : 8½; and of those of four alternations in the Norwich collection are 1 : 26½. The order in which different deposits succeed each other in calculi has been examined by Dr. PROUT, with the view of elucidating the changes in the economy upon which this order depends. He found that the frequency of alternation of uric acid and oxalate of lime is nearly equal; that oxalate of lime follows urate of ammonia more frequently than uric acid; that the general ratio in which phosphates succeed other deposits in all the collections is 1 : 4½; and that a decided deposition of the mixed phosphates in calculi is not followed by other deposits.

145. xi. *Fibrinous calculus* was first described by Dr. MARCET. It is stated by Dr. PROUT to be usually of an amber colour and waxy consistence, with more or less of a fibrous texture. As to the chemical tests for this and the other calculi described above, I must refer the reader to the *Table* given above from Dr. BENGE JONES (§ 130); and to the chapter on "The Chemistry of Urinary Concretions," in Mr. COULSON's able work already referred to.

[*Chemical Composition of Calculi in the United States.*—It is to be regretted that so little attention has been paid to the chemical analysis of our calculi. So far as they have yet been ascertained, they are as follows:

Of the 15 calculi, removed from as many patients, by Dr. J. MASON WARREN, of Boston, 2 were of pure lithic acid; 1 lithic acid with layers of phosphates; 3 phosphate of lime; 3 oxalate of lime; 2 oxalate of lime, with phosphates; 1 cystic oxide; 2 triple phosphates.

Of the 22 calculi, in the Museum of the Boston Society for Medical Improvement, from various parts of New England, 5 consist of uric acid, surrounded in one by thin layers of oxalate of lime and the mixed phosphates; 3 of uric acid and the urates; 1 of urate of ammonia; 2 of uric acid and mixed phosphates; 1 of urate of ammonia and mixed phosphates; 1 of uric acid and urate of ammonia, inclosed by mixed phosphates; 1 of uric acid and mixed phosphates, with urates of potash and ammonia; 1 of urate of ammonia and oxalate of lime; 2 of phosphate of lime; 2 of mixed phosphates; 2 of oxalate of lime; and 1 of oxalate of lime and mixed phosphates.

Of 5 operations for stone, performed by Professor F. H. HAMILTON, of Buffalo, 1 was a fusible calculus, with oxalate of lime as a nucleus; 1 urate of ammonia; 1 fusible calculus with carbon-

ate of lime; 1 fusible calculus with traces of lithrates.

Of 22 calculi removed by Professor VAN BUREN, of New York, 2 were pure lithic acid; the rest were compound in their character, principally triple phosphates.

Of 14 cases of lithotomy performed by Dr. J. DICKSON, of Alleghany, Pennsylvania, in 13 the stone was lithic acid; in 1 phosphate of lime. Of the cases of urinary disease occurring in Western Pennsylvania and Ohio, the same surgeon states that the great majority labour under the lithic acid diathesis, about ten per cent. under the phosphatic, and about five per cent. under the oxalic.

Dr. CHARLES FRICK, of Baltimore, states that the great majority of urinary concretions in that city are composed either of uric acid or oxalate of lime, the phosphatic being very rare; of 32 separate specimens of calculi removed by Professor N. R. SMITH, of Baltimore, the same chemist found, on analysis, 4 of pure uric acid; 4 of pure urate of ammonia; 10 of pure oxalate of lime; 6 of phosphates; 2 of urate of lime; 1 of pure cystine; 15 contained uric acid, either alone or combined. The patients came from different parts of the Middle and Southern States.

Of 4 cases of calculi removed by Dr. OGIER, of Charleston, South Carolina, 2 were mulberry, and 1 principally phosphate of ammonia and magnesia.

Of 71 separate specimens of calculi removed by Dr. DUDLEY, of Kentucky, the results of analysis by Professor PETER, arranged with reference to the nuclei and bodies of the calculi, are as follows:

1.	Predominance of the uric acid in the nucleus in	36	6
2.	" of urate of ammonia	"	41
3.	" of oxalate of lime	"	14
4.	" of earthy phosphates	"	8
5.	" of cystine	"	3
6.	" of foreign substance	"	4
			<u>71</u>

*Simple Calculi*; whole number, 31.

1.	Predominance of uric acid in the concretion	5
2.	" of urate of ammonia	9
3.	" of oxalate of lime	9
4.	" of earthy phosphates	6
5.	" of cystine	2
		<u>31</u>

*Compound Calculi*; whole number, 40.

II. Number of specimens in which uric acid predominated:

Number of calculi having a nucleus of uric acid, 1.

A. Nucleus of urate of ammonia:

1.	Bodies principally oxalate of lime	10
2.	" urate of ammonia	7
3.	" uric acid	3
4.	" fusible	9
		<u>29</u>

III. Number of specimens in which oxalate of lime predominated:

A. Nucleus of oxalate of lime:

1.	Bodies principally phosphates	2
2.	" uric acid	2
3.	" urate of ammonia	1
		<u>5</u>

IV. Number in which earthy phosphates predominated:

A. Nucleus of earthy phosphates:

1.	Bodies principally phosphate of lime	1
2.	" fusible	1
		<u>2</u>

V. Number in which fusible phosphates predominated:

A. Nucleus of foreign substances:

1.	Bodies, triple phosphates, phosphate of lime, and urate of ammonia	1
2.	Bodies fusible, trace of uric acid and urate of ammonia	1
3.	Bodies fusible	1
		<u>3</u>

Total..... 40

The conclusions arrived at by Dr. PETER are, first, that calculous diseases are more frequent in the limestone than in the freestone regions of Kentucky; and, secondly, that there is a larger proportion of phosphatic and oxalate of lime deposits, with a greater number of nuclei of urate of ammonia, and fewer of pure uric acid in the limestone than in the freestone districts of the State, or where the water is free from calculous matter.

Dr. E. B. HASKINS has analyzed 176 Tennessee calculi, of which 107 were duplicates, the weight of the concretions ranging from 2 grains to 1027, the average being 91 grains, and the aggregate 16,038; the lowest specific gravity 1.198, the highest 1.812; average, 1.509. Of this number there were of

Earthy phosphates, 9,	with an average spec. gr. of	1.338
Urates, 5,	"	1.694
Oxalate of lime, 1,	"	1.689
Mixed, 30,	"	1.533

*Chemical Results.*—The whole number of calculi analyzed was, as already stated, 176, 107 being duplicates, leaving thus 69 separate specimens. The results are arranged with reference to the nuclei and bodies of the concretions:

1.	Predominance of the urates in the nuclei, 43 (3 duplicates)	45
2.	Predominance of oxalate of lime in the nuclei, 20 (6 duplicates)	14
3.	Predominance of triple phosphate in the nuclei, 101 (95 duplicates)	6
4.	Predominance of phosphate of lime in the nuclei	9
5.	Predominance of uric acid in the nuclei, 4 (3 duplicates)	1
6.	Predominance of foreign matter	69

The number of *simple calculi*, or nuclei without bodies, was 44. The number of compound concretions, or those having a body upon a nucleus, was 132, of which 78 were duplicates, leaving 54 separate specimens.

1.	Predominance of urates in the bodies	8
2.	" of triple phosphates in the bodies, 93 (75 duplicates)	18
3.	Predominance of oxalate of lime in the bodies	15
4.	" of phosphate of lime in the bodies, 15 (3 duplicates)	12
5.	Predominance of uric acid in the bodies	1
		<u>54</u>

The *compound calculi*, or those having both a body and nucleus, may be arranged as follows:

I. Number of specimens in which urates predominated:

1. Number of calculi having nuclei of urates 8

II. Number of triple phosphate bodies, 93 (75 duplicates):

1.	Number having nuclei of triple phosphate, 76 (75 duplicates)	1
2.	Number having nuclei of urates	12
3.	" of oxalate of lime	5
		<u>18</u>

III. Number of phosphate of lime bodies, 14 (2 duplicates):

1.	Number having nuclei of urates	7
2.	" of triple phosphate, 4 (2 duplicates)	2
3.	Number having nuclei of oxalate of lime	3
		<u>12</u>

IV. Number of oxalate of lime bodies:

1.	Number having nuclei of oxalate of lime	2
2.	" of urates	12
3.	" of foreign matter	1
		<u>15</u>

V. Number of uric acid bodies:

Number having nuclei of urates 1

Total..... 54

[\* Dr. HASKINS uses the term "urates" instead of "urate" of ammonia, because he has never found this substance to exist in any other form than in combination with urate of lime, or of soda, or both.]

These results are very similar to those of the Kentucky calculi. Excluding duplicates, we have 71 Kentucky specimens, and 69 Tennessee. Of the former, the nuclei in 6 were composed nearly entirely of uric acid, and in 8 of earthy phosphates; in the latter, of uric acid in 1, and of earthy phosphates in 8.

*Bases of the Urates*.—Dr. HASKINS analyzed 84 specimens of the urates, with a view to determine their bases, and the results arrived at were as follows: Ammonia was found in all; lime with ammonia in 83; soda with ammonia and lime in 55; and soda with ammonia alone in 1. For magnesia and potash no search was made. The ammonia largely predominated over both of the other constituents. Urate of lime, which has generally been regarded as a rare ingredient of urinary calculi, was present in 83 of the examinations, and usually existed in larger quantities than the soda.\*]

146. VI. CAUSES OF URINARY CALCULI.—The causes of urinary concretions may be inferred from what I have stated above with reference to the pathological conditions occasioning the several forms of urinary deposit, the concretions taking place in different parts of the urinary apparatus being merely early deposits in those situations of the same constituents as are precipitated by the urine after being discharged from the body. Whether the concretions are formed within the body, or the deposits take place after the urine is evacuated from the body, many, indeed most of their causes, are the same; the states of the urine which produce them arising chiefly from, (a), age and habits of life; (b), from climate, locality, and race; (c), from diet and regimen; (d), from morbid digestion and assimilation; (e), from pathological states of the kidneys, and from the metamorphosis of tissues and of blood-globules, in connexion, (f), with constitutional and vital conditions. But it may be asked, Wherefore should concretions form within the urinary organs, consisting of the same or nearly the same constituents as are deposited from the evacuated and cold urine? To this question the chief answer must be that which I have stated above (see § 80-4), namely, that low states of vital power favour the more rapid evolution of that portion of vital emanation which all secretions (the urine as well) possess for a shorter or longer period after secretion, according to the amount of vitality endowing the secreting organs, in connexion with the extent of change in the constitution of the secretions, with their accumulation and retention, and with the amount of vital influence and animal heat retained by them, or furnished to them during their retention. Although these causes of urinary deposit and concretion have been above considered with reference to the deposits found after the urine is evacuated, certain topics connected with them, more especially with the formation of calculi, require a more particular notice than they have yet received.

147. Deposits from the urine, more or less abundant, after evacuation may proceed for a very long time without any deposit taking place within any part of the urinary apparatus. This immunity from the formation of calculi may arise either from the circumstance of the urine having not been saturated with the substance or sub-

stances which usually pass into calculus, or from the states of vital power being unfavourable to the formation of renal or vesical concretions, or from the absence of other causes which favour such formation.

148. i. *Age and Sex*.—The liability of children to calculi has been remarked from the days of HIPPOCRATES; and Mr. COULSON quotes the "*Methode of Physick*," in which the author, PHILIP BARROUGH, remarks that "stones in the bladder do engender oftener in children than in older folk."—(*Lib. iii., c. 41, editio quinta*, 1617.) Although the liability of strong and well-fed children may not be greater than that of any other class of subjects, yet there is no doubt of weakly, unhealthy, and ill-fed infants and children being more frequently affected with gravel and calculi than older persons. Of 478 operations for stone in the Norwich hospital during a period of forty-four years, 227 were in children under fourteen years. According to Dr. PROUT, the following is the relative frequency of urinary calculi at different ages: Under 10 years of age, 500; from 10 to 20, 192; from 20 to 30, 104; from 30 to 40, 94; from 40 to 60, 112; from 60 to 70, 97; and from 70 to 80, 12. Taking into consideration the numbers of those living at the most advanced ages, urinary concretions are more frequent at these ages than in the prime of life.\*

149. Females, notwithstanding their more sedentary habits, and their liability to retain their urine for long periods, are less frequently subject to calculus than males. This is partly owing to their temperate and abstemious habits, and partly to the facility with which a small calculus may escape from the female bladder soon after its descent from the kidneys, and before its retention in the bladder has enabled it to acquire a great size by successive depositions around it. The female urethra, admitting of greater dilatation, and being less complex than the male urethra, and otherwise differently connected and circumstanced, allows the spontaneous passage of calculi which would be retained in the male bladder, and could be removed only by an operation.

150. ii. *Habits of Living*.—Sedentary habits and luxurious feeding are more or less influential, according as they may be associated with other causes, in occasioning urinary concretions. The former impairs very remarkably the functions of the skin, and prevents that amount of blood-depuration which these functions effect; the latter furnishes the pabulum or source from which urinary concretions are in great part derived. When these habits exist in, or are conjoined with, a gouty diathesis, the occurrence of gravel or calculi is often observed; and much more remarkably when a meat diet and malt liquors are very liberally indulged in; for this diet, especially the more nitrogenized kinds, forms urea and the urates in great abundance, and generates either gout, or gravel, or calculi, or both, and subjects the kidneys to a much greater amount of depurating function by increasing the

\* M. CIVIALE in his "*Treatise on Calculous Affections*," states that of 5376 cases, 2416 were children, 2167 adults, and 793 old persons. He says that 1946 occurred before the age of ten, 943 from ten to twenty, 460 from twenty to thirty, 830 from thirty to forty, 391 from forty to fifty, 513 from fifty to sixty, 577 from sixty to seventy, 199 from seventy to eighty, and 17 after eighty. Instances of calculus have been recorded from birth, and very soon after birth. Mr. COULSON operated for stone on a child of eighteen months, and upon a man of eighty years of age.

[\* For the above details we are indebted to the able work of Professor GROSS on "Diseases of Urinary Organs."]

quantity of morbid materials which require removal from the blood.

151. When the skin ceases to discharge its share of this process of blood-depuration, an increased demand is made upon the kidneys, and an increased supply of the constituents of urinary deposit is furnished to these organs. It will thus appear very manifest that, as the same causes as are more or less concerned in the production of gravel and calculi are also productive of gout, these two diseases must be frequently associated in the same person. The association of calculi with rheumatism is much less frequent than with gout; but when it occurs it may be imputed in great measure to a similar combination of causes.

152. iii. *Climate, locality, and race* very considerably influence the occurrence of urinary concretions. It is very difficult in many instances to explain the operation of these; but there is no doubt of these maladies being more frequent in humid, temperate, and changeable climates, than in very warm or very cold countries; in some localities than in others even of the same country; and in the white than the dark races. Holland, France, England, Germany, have been regarded as furnishing the greatest number of calculous cases; but other countries are by no means exempt from them. Within the tropics, urinary concretions are more rarely observed than in temperate countries, and chiefly or only in the very young and ill fed. The marked infrequency of these concretions in the dark races is chiefly to be imputed to the very small proportion of animal food constituting the diet of these races, especially within the tropics, and to the greater activity of their cutaneous functions.\*

\* Dr. GROSS (on the *Diseases and Injuries of the Urinary Bladder*, &c., 8vo. Philad., 1851) confirms the rare occurrence of urinary calculi in the coloured races. In ten years he never met with an instance of gravel or of stone in a coloured person. Dr. DUMLEY, in Kentucky, who has the largest practice there, never operated for stone on more than two or three persons, who are constantly exposed to hard labour, and fare often upon the coarsest food. Dr. GROSS states that urinary calculi are rare in Canada, in Texas, Mexico, and California; that in the United States a larger number of children are subject to calculi in Kentucky, Ohio, Tennessee, and Alabama than in any other part; and that the inhabitants of Missouri, Iowa, Wisconsin, Michigan, Indiana, New York, and New Jersey are comparatively exempt.

It is proper, in this connexion, to give a more detailed account of the results of Professor GROSS's researches in regard to the prevalence of stone in the bladder and calculous disorders in the United States. From these it appears that the great stone regions of this country are, as far as is at present known, Kentucky, Tennessee, Virginia, Ohio, North Alabama, and perhaps Missouri, the disease being comparatively infrequent in all other sections of the country. The causes of these differences are as yet not satisfactorily known. They cannot be satisfactorily explained, on the ground of difference of climate, geological formation, or habits of life, nor in the food, drinks, and occupations of the inhabitants; for in these respects, for example, there is but little difference between Kentucky and Indiana, yet calculous affections are very common in the former and very rare in the latter. Corn-bread and pork constitute the staple articles of food throughout the Southern and Western States, with unleavened biscuit of wheat, potatoes, hominy, cabbage, turnips, and tomatoes, with coffee, tea, and milk at breakfast and supper. Eggs, poultry, and milk are also freely used. In the calculous districts lime-water generally prevails, and is used freely by nearly all the inhabitants; but the same is true also of some parts of New England and Canada, Indiana, Illinois, &c., where stone in the bladder is rarely met with. The Germans are remarkably exempt from calculous affections, and they consume large quantities of malt liquors. The climate is essentially the same in the calculous and some of the non-calculous districts. The prevalent diseases in the calculous regions are intermitting and remitting

The imputed infrequency of calculi in very cold countries is accounted for with much difficulty, especially as animal food is generally freely used. The active employments followed by the natives of these countries, a fish diet adopted by many, and other unascertained influences, may combine to produce this partial immunity. The greater prevalence of calculous diseases in Norfolk than in any other county in England is fully admitted. Mr. CROSSE, the eminent surgeon of Norwich, considered this prevalence to be owing to a combination of causes—to the variability of the climate of Norfolk, to the prevalence of northeast winds, and more especially to the frequency of dyspepsia and acidity in the stomach, and to the consequent superabundance of uric acid in the urine. SOEMMERING states that calculous and gouty affections are unknown, or most rare, in some situations bordering on the Rhine. LIEBIG imputes this immunity to the Rhenish wines, which contain a considerable quantity of the bitartrate of potash. This salt, he contends, changes in the progress of digestion to the carbonate of potash, and acts the part of an alkali.

153. It was formerly believed that the waters of a locality had some influence in producing urinary concretions. This opinion has, however, been controverted by several modern writers, and it is undetermined whether or no the waters which abound in calcareous or other mineral substances have any effect in occasioning urinary

fevers, neuralgia, pneumonia, dysentery, rheumatism, and dyspepsia; and urinary deposits of all kinds, especially the lithic acid and urates, are common. The causes, then, which favour the formation of stone in the bladder remain, for the most part, undetermined, though there can be no doubt that such affections must be influenced to a greater or less degree by climate, food, and drinks, occupation, &c. We believe it will yet be made to appear that the hygrometric state of the air (*a high dew-point*) is one of the most efficient predisposing causes. In all the New England States calculous affections are very uncommon, although much of the drinking-water is strongly impregnated with lime. The number of lithotomy cases that fell to the charge of Professor J. C. WARREN, during a period of forty years, was only 25; and he is said to have been the only surgeon in Boston who performed that operation during that whole time. Only three of these cases were natives of Boston; the others came from different parts of New England. Dr. NATHAN SMITH was of opinion that more cases of the disease originated in Vermont and Maine than any of the other New England States, and these States abound in limestone more than any of the others. Up to 1855, Dr. J. M. WARREN, of Boston, had operated for stone 13 times; Dr. V. MOTT, of New York, 163 times; Dr. F. H. HAMILTON, of Buffalo, 5 times; Dr. A. TROWBRIDGE, of Watertown, N. Y., 18 times; A. MARCH, of Albany, 16 times; W. PARKER, of New York, 24 times; Professor VAN BUREN, of New York, 20 times (besides several operations by Drs. CARNOCHAN, POST, BUCK, WOOD, HOFFMAN, WATSON, &c.). During 17 years and a half (1837 to 1855) only 14 cases of stone in the bladder were treated in the New York Hospital, which receives annually about 3500 patients. In the Pennsylvania Hospital at Philadelphia, from the time it was opened for the admission of patients, in 1772, till May, 1848, 100 years, only 83 patients were cut for this disease, of which few originated in Philadelphia or vicinity. Up to 1842, Professor GIBSON, of Philadelphia, had operated for stone 50 times; Dr. J. RHEA BARTON, 36; GEORGE MCCLILLAN, 30 (and before his death, 50). Dr. PANCOAST has had (1856) 41 cases; Dr. J. DICKSON, of Alleghany, Pennsylvania, has operated on 14 cases in the last seven years.

Dr. METTAUER, of Virginia, has performed the operation for stone 91 times; Dr. P. C. SPENSER, of Petersburg, Va., 24 times; Dr. DUDLEY, of Kentucky, 207 times; Dr. GROSS, 40, &c. These constitute the vast majority of operations of this kind performed in the United States during the last 30 years.

With regard to age, American statistics are extremely deficient. Of Dr. DUDLEY's patients, three fourths were under 15 years; and of 27 Kentucky cases of Dr. GROSS, 14 were under this age.]

calculi. The subject has not been investigated with precision, and the arguments on both sides are loose, and indeterminate as to facts.

154. It has been contended by Mr. COPLAND HUTCHINSON and Sir G. BALLINGALL that sailors and soldiers are almost exempt from urinary concretions. But when it is considered that both sailors and soldiers are of those ages in which these concretions are seldom observed, the extent of this exemption cannot be great. Whatever it may be, the activity of the digestive, assimilating, and depurating functions in these classes and at their periods of life evidently constitutes its chief cause.\*

155. iv. *Diet and regimen* has more influence on the frequency of calculous diseases than is generally believed. The evil produced by animal food used in excess—and many use it in excess relatively to the amount of exercise taken—has been already adverted to (§ 150). Highly nitrogenized animal diet furnishes a rich and an abundant chyle, which, during its circulation in the blood through the several viscera, becomes oxidized and otherwise changed, and, in various states of metamorphosis, under the influence of vitality, originates the most important parts of those materials which require a continued elimination from the blood; and if this end be not attained by the active discharge of the several depurating functions—by the kidneys, skin, mucous surfaces, &c.; and if it be not promoted by exercise sufficient for its fulfilment, an accumulation of these materials in the blood takes place, and, becoming more and more highly animalized and morbid, and irritating by their retention and accumulation, occasions serious diseases, among which Gout (as shown in that article, § 33-42) and urinary concretions are the most common.†

156. v. *Metamorphosis and waste of tissues*, &c.—It will be seen, from what has been stated above (§ 41-5), that Baron LIEBIG and Dr. GOLDING BIRD have attributed the solid materials dissolved in the urine, with their deposits and concretions, to the chemical combinations of the elements resulting from the metamorphosis and waste of the tissues in the course of the regeneration and nutrition of these tissues. But if we take into consideration the great amount of these materials discharged into the urine, and refer them only to the sources from which these writers derive them, it must follow that these tissues ought to be renewed several times every successive year of existence! It must be admitted that the metamorphosis and waste of the tissues—to which I would add similar changes in the red globules of the blood also—furnish some part of these materials; but a much greater share is supplied by the food, by the chyle conveyed into and

circulating with the blood, and by the successive changes therein produced, under the influence of vitality; the regeneration and nutrition of the tissues requiring only a small but appropriate portion of the constituents thus supplied, the less appropriate materials being eliminated from the circulation by the kidneys, skin, and other depurating organs.

157. vi. *Indigestion, fermentation, and mal-assimilation* are causes of urinary deposit and concretion intimately connected with a too full, rich, or unwholesome diet. Numerous articles of food are indigestible in their nature, more especially if not sparingly partaken of, and are liable to become rancid in the stomach, and to occasion rancid eructations; while others are more disposed to fermentation, and to generate acidity in the stomach and bowels; both rancidity and acidity sometimes occurring simultaneously, according to the nature of the food, to the quantity taken, and to the powers of digestion and assimilation. Owing to undue and superabundant quantity, or to improper quality, or to both, an imperfectly digested and assimilated chyle is formed and carried into the circulation, furnishing the material elements of disease, and more especially of urinary concretions. But it is not only to full diet, much animal food, or to unwholesome aliment, that these concretions may be remotely imputed, but also to insufficient food, especially in early life. In this latter case the powers of life are so reduced by the insufficient nourishment as to imperfectly digest and assimilate what is taken, and the blood is thereby diminished in quantity and impaired in quality.

158. vii. *Constitutional and vital conditions* manifestly combine with the preceding causes in occasioning concretions in the urinary apparatus. These conditions I have viewed above (§ 45, 157) as consisting of more or less manifest impairment, not only of the digestive, and assimilating, and depurating functions, but also of the vital endowment throughout the frame. This general impairment of vital power accounts for the prevalence of urinary excretions in delicate and in imperfectly or improperly fed children, or previously to puberty, and in the aged, and for the comparative rarity of these concretions in persons during the prime of life, or during the period of sexual activity, and in those who are neither over-fed or under-fed, and who are not exposed to the remote causes above mentioned.

159. viii. *Bodies or substances introduced or passed into any portion of the urinary apparatus* are liable to become the nuclei around which urinary concretions may form and increase by successive deposits. Numerous instances of bodies having passed into the bladder, and become the nuclei of large calculi, are recorded by medical writers. To these it is unnecessary to refer, as they are sufficiently known; but they satisfactorily prove that these bodies give rise to the first act of deposition or crystalline formation by the urine, when more or less loaded or saturated with the constituents of urinary deposit and concretion.

160. ix. *Morbid states of some part of the urinary passages* may be attended by an extravasation of a minute quantity of blood, or by a purulent or mucous discharge, which, either in the uriniferous tubes, or in the pelvis of the kidney, or in the bladder, may become the cause of deposit, by attracting the uric acid, the urates, or

[\* There is good reason to believe that the use of *sorrel* and the footstalks of the *rhubarb* plant favour the production of *oxalate of lime* deposits, as they both contain oxalic acid, combined in excess with potash. The free use of *sugar* may also act as a powerful predisposing or exciting cause.]

[† Dr. W. P. C. BARTON, formerly at the head of the Medical and Surgical Bureau at Washington, expresses the opinion that sailors are entirely exempt from calculous diseases. The same opinion substantially is expressed by Surgeons FOLTZ, LICHTENBERGER, GREEN, HORN, CORNICK, and others of the United States navy. Urinary deposits occur among landmen and marines, but rarely, if ever, among those who have been brought up at sea. The same singular immunity exists among the seafaring people of all nations. The cause assigned by our author, viz., the activity of the digestive, assimilating, and depurative functions, is doubtless the principal one.]

other saline constituents of the urine, and form the nucleus of successive deposits. It is not improbable that a change, such as I have just stated, may take place in some portion of the kidney, or even in some other part of the urinary apparatus, owing either to external injury, or to other causes, and, by favouring the concretion of the superabundant saline constituents, or uric acid in the urine, thus form the nucleus of a renal calculus, which may either remain long in the kidney, and increase slowly, or pass into the bladder, and become, as in the case of a foreign body, the centre around which successive and large deposits collect. Most calculous concretions are thus formed, their nuclei and earlier deposits being formed in the kidneys, their chief increase taking place in the bladder.

161. *Inferences.*—The efficient causes of urinary calculi may doubtless operate differently in different diatheses and constitutions, and in different circumstances, more especially in determining the *nature of the deposit*; but there is some reason for concluding, 1st. That a diet composed chiefly, or of a large proportion of animal food, tends to increase the quantity of the uric acid and urates, and to favour their deposition, and to lessen the generation and deposition of the phosphates; 2d. That rancid and accescent ingesta, and rich sauces, exert nearly similar influences to the foregoing; 3d. That whatever promotes the functions of the skin tends to prevent the deposition of uric acid, and to favour that of the phosphates; and, 4th. That indolence and indigestion tend to increase the deposition of uric acid and to lessen that of the phosphates, both by producing acidity of the *prima via*, and by impairing the functions of the skin and liver.

162. x. *The origin and growth of urinary calculi* was first clearly stated by VAN SWIETEN (*Comm. in Aph. Boerh.*, 1414). He remarks, that "stones proceed from elementary principles, which, in a state of solution, previously existed in the humours, and when these meet with an indissoluble basis, they fix themselves thereto, and form a calculus, which continually increases in bulk from the application of fresh calculous matter." This statement is probably correct as far as it goes, but various topics connected with the original nature and primary formation of urinary concretions are not comprised in it. Dr. GOLDING BIRD and others contended for an oxaluric diathesis, which gives rise to the secretion of oxalic acid and oxalates from the uric acid and urates existing in the blood. Dr. OWEN REES has opposed this doctrine, and has argued that the oxalic acid and its compounds are not produced from uric acid or from urates already existing in the blood, but that the change is effected in the urine, after its secretion by the kidney. "In this latter case the *uric acid* in combination will be secreted as such into the urine, but by after processes, occurring either in the urinary passages, bladder, or chamber vessels, it will present itself converted into a compound of the oxalic acid." If this be really the case, then we must admit that the state of system in which we observe a tendency to the formation of oxalate of lime in the urine must be considered identical with that accompanying the uric acid diathesis, and as requiring the same treatment, and the same precautionary measures.

163. Dr. ALDRIDGE, of Dublin, has shown the manner in which uric acid and its compounds

become decomposed into an oxalic salt. "He has proved that uric acid may be theoretically considered as representing the elements of oxalate and carbonate of ammonia, hydrocyanic and formic acids, if we merely add to its atoms the elements of water in varying proportions. He has demonstrated that this really occurs; for, by heating urine, and in some cases by evaporating it, he has succeeded in causing a deposit of oxalate of lime, while evidence of the presence of hydrocyanic and formic acids could be obtained from the fluid." (O. REES, *on Calc. Dis.*, &c., p. 5.)

164. a. The chemical reasoning, Dr. O. REES remarks, which shows how unlikely it is that oxalate of lime should exist in the blood, is quite borne out by pathological conditions. He therefore concludes, in opposition to Drs. GARRUD and G. BIRD, that, whenever oxalate of lime is found in the urine, it should be regarded as *produced after secretion*, and that there is no such thing existing as an oxalic diathesis. LENMANN, who has also opposed the opinions of the late Dr. BIRD, has stated that morning urine, left to stand some hours, often contains oxalate of lime in quantity, when the fresh urine did not contain any trace of it. WOHLER and FRERICHs found that the urates when injected into the blood produced oxalate of lime in the urine. Dr. O. REES thus "regards oxalate of lime merely as uric acid, or urate altered after secretion," and that the lists of calculi contained in museums will show that the uric acid diathesis produces nearly the whole of the calculous diseases observed, especially by forming the nuclei of most of those which are formed of other constituents.

165. The greatly increased quantity, and the insolubility of uric acid, are quite sufficient causes of the deposit of it in the kidneys, especially when in excess, and in the circumstances about to be noticed (§ 167, 169), without calling in the aid of any other agency. If the deposition of the uric acid in the calculous form in the kidneys, where it originally takes place in the great majority of cases, if not in all, and if the calculus, having passed into the bladder, "fail to produce any great irritation of the vesical mucous membrane, then it will be enlarged by the continued deposition of uric acid layers; but if, as is generally the case, this calculus irritate the surfaces, then the bladder becomes inflamed, and the mucous membrane throws out an alkaline fluid, which now decomposes the ammoniacal salts contained in the urine and liberates the ammonia. This may unite to a portion of uric acid, forming urate of ammonia, so that the next layers of the calculus may consist either entirely of urate of ammonia, or of that salt in admixture with uric acid. The changes may cease here, and the calculus, though it increase under these conditions, be thus compounded merely of two constituents. The next change may, however, occur, and may determine the formation of a more compound form of concretion; and this will consist in the pouring out of an *excessive* quantity of alkaline secretion by the inflamed mucous surface. This will not only completely neutralize the acidity of the urine, but cause, like all alkaline solutions, a precipitation of the earthy phosphates." (*Op. cit.*, p. 28.) These will coat the calculus, intermixing or not with the urate of ammonia, or uric acid, according to the amount of secretion and its alkaline character.

166. b. In respect of the *phosphatic deposits*

and *concretions*, Dr. O. REES farther contends for their production uniformly from irritation or disease of the urinary mucous surfaces, and for the presence of uric acid or some other form of concretion being a sufficient cause for the formation of phosphatic layers on a calculus. In answer to the questions as to how phosphatic calculi are formed when *no* other calculous matter can be detected as a nucleus, and what were the conditions antecedent to the phosphatic deposit in such cases, he states that these calculi are rarely met with, and when present are the consequences of disease of the mucous membrane of the bladder, and where, of necessity, the alkaline secretion consequent upon irritation of this membrane is poured out from it in quantity. "This state of things often follows upon enlargement of the prostate with stricture, so that the bladder is not easily emptied." The retained portions of urine will have their earthy phosphates precipitated by the alkaline secretion of the diseased mucous membrane, and the formation of a calculus result. Hence it follows, 1st, that the presence of other calculous matters, by irritating the bladder, causes a deposition of the earthy phosphates, these matters forming the nuclei around which the phosphates are deposited; 2d, that the alkaline secretion from the irritated urinary mucous membrane occasions a concretion, independently of such nuclei, by precipitating the phosphates. It was long ago remarked by Dr. PROUT, that these salts, when present, were always found covering other deposits, and rarely alternating with them; so that, if the nucleus were phosphatic, the crust would be the same, and no covering be found of any other form of calculous matter.

167. Since uric acid is the nucleus of the great majority of calculi, the conditions under which this deposit occurs should be considered. In persons subject to the continued excretion of uric acid and the urates, the quantities discharged may be very great, without showing any tendency in these substances to concreate into the calculous form. These materials may even give rise, from their abundance, to attacks of "gravel," without any considerable calculus being formed, and very common means may give relief. In other cases, the deposits in evacuated urine may be in far less proportion, and yet the tendency to concreate into calculi be very early shown. These facts, as Dr. O REES contends, seem to prove that, in order to produce a calculus, some condition must be present besides that which we recognise in a tendency to the deposit of solid matter from the urine. It is necessary to bear in mind what has been said above (§ 166) respecting the chemical effect of the alkaline secretion from the inflamed urinary mucous membrane, upon which he places more stress than the proofs may be supposed to warrant. But besides possessing the imputed chemical qualities, Dr. O. REES infers that the secretion from the inflamed membrane evinces mechanical conditions which must influence the result where a tendency exists to deposit solid matters from the urine, and that the secretion from the inflamed mucous surface, being of a tenacious character, and containing fragments of epithelium and mucous corpuscles, will cause the particles constituting the deposit to unite and form a nucleus or concretion of successive deposits.

168. Instead, therefore, of viewing the earthy

phosphates as secreted by the mucous membrane, Dr. O. REES believes that this membrane acts merely through its alkaline secretion, which precipitates the earthy phosphates from the urine; and he farther infers, that the same conditions noticed with regard to the bladder are present also in the kidneys, and that it is to these conditions in these latter organs, rather than to what exists in the bladder, that we ought to look for the chief cause of the formation of nuclei, and the very general origination of calculi in the kidneys. "At any rate, this would appear to apply so far as the production of a nucleus is concerned." The mechanical conditions presented by the pelvis and urinary tubules certainly are far more favourable to the agglutination of deposits than those observed in the bladder; for these are smaller conduits and cavities, and in the immediate vicinity of the tubules the first deposited matters are brought in intimate contact with the spheroidal epithelium, which under irritation rapidly desquamates and is more especially liable to entangle floating particles of deposit, and so to favour the formation of calculus. "The reasoning," Dr. O. REES adds, "I have used with respect to the bladder applies with full force to the formation and growth of calculi in the kidney. From what I have now adduced, I would submit, that if we except cases in which are formed the four following rare substances, viz., cystine, carbonate of lime, silicic acid, and uric oxide, we may consider all calculous disease as originating in the gouty or uric acid diathesis." (*Op. cit.*, p. 38.)

169. A nucleus may form in any part of the urinary canals; but the tubules are by far the most frequent seat of the original deposit. Small particles are sometimes found in the secreting structure; and if these do not pass onward to the tubular structure, they may increase by deposit of successive layers until a calculus of considerable size is produced. In this case a portion of the organ, corresponding to the development of the concretion, may be destroyed, and symptoms varying with circumstances be produced. The first deposit may, however, pass lower down into the tubular structure, or thence into the pelvis of the kidney, and either remain in either of these situations or pass along the ureter into the bladder, causing more or less distress, in some cases extreme suffering, during its passage; and having reached the bladder, it may be expelled through the urethra by the stream of water, or remain in the bladder and become the nucleus of a large concretion.

170. VII. SYMPTOMS OF URINARY CALCULI.—i. *In the Kidneys*.—The symptoms produced by a calculus or calculi in the kidney vary with the size, form, or smoothness of the stone, its situation in the organ, and the constitution, temperament, and diathesis of the patient. The calculus may remain in the kidney, or even several may remain, or pass thence into the bladder. If it remain, either relief of more or less severe symptoms may take place after a time, owing to a cystic covering forming over it, or disorganization of the kidney sooner or later supervenes and destroys the patient. If the calculus remain in the kidney and become encysted, more or less severe pains in the loins or in one or both sides, often extending down the thigh or thighs, and sometimes upward under the shoulder blades, colicky pains in the abdomen, nausea, vomiting,

hæmaturia, and frequent calls to pass the urine, are complained of. These symptoms may gradually subside, and they may recur oftener than once, after indefinite periods and with various degrees of severity, especially after sudden or severe exertion, particularly when the trunk of the body has experienced a shock or concussion. The pain often becomes dull or aching, or is seated chiefly on one side of the abdomen, or extends to the groin, or a sympathetic pain, resembling neuralgia, is experienced at a distance from the region of the kidney, and not unfrequently extends to the testicle of the affected side. After a lengthened period, and after frequent recurrences of the symptoms in slighter grades, the patient either experiences an immunity from farther suffering, or complains only of slight and wandering or recurring pains, which often may be traced to one or other kidney.

171. In less favourable cases of retention of the calculus or calculi in the kidney, the symptoms assume the features described when treating of *Inflammation of the Kidney* (§ 48, 49, 59, *et pluries*), and of *Pyelitis* (*art* KIDNEY, § 174–183, 192–198, *et pluries*), and are fully described, with the several relations of this subject, in the article, and more especially at the places now referred to. I may, however, remark at this place the difficulty of diagnosis between a calculus in the right kidney and the passage of gall-stones. At the commencement of the irritation produced by a calculus in the right kidney, and when the symptoms are very severe, or when a calculus has entered the ureter from the pelvis, the complaint may readily be mistaken for gall-stones, especially when the vomitings, pain, and spasm are very urgent, and if all the symptoms be not carefully examined. I have found it even recently very difficult to determine at first as to the seat of disease; and this difficulty is increased if there be, as there frequently is, pre-existing disorder of the biliary functions, more especially interruptions of the biliary secretion, or some degree of jaundice. As the symptoms of renal calculi proceed, and especially as the calculi pass into or along the ureter, the nature of the complaint becomes more manifest, and indeed is most frequently so from the commencement, especially when the symptoms attending the secretion and excretion of urine are well marked, and blood-globules are observed in the urine. When the hæmaturia is very considerable, especially after exertion or sudden movement of the trunk, in connexion with the other symptoms of *calculous nephritis* (see KIDNEY, § 48, *et seq.*), the nature of the case is evident; and if the draining of blood continue for a considerable time, and the local symptoms are very acute, the oxalate of lime calculus is not unfrequently its cause.

172. ii. The *diagnosis* of renal calculus is rendered most difficult in the gouty and rheumatic diathesis, and in cases of chronic disease of the urinary bladder and prostate gland; for the pain in one or both sides of the lumbar region may be rheumatic or gouty, or may proceed from cachectic nephritis, or BRIGHT'S disease, or from pyelitis or abscess of the kidney, occurring either primarily, or caused by calculi, or following chronic uro-cystitis or stone in the bladder, or even from inflammation or abscess of the lumbar muscles. If any tumour or swelling be detected in the region of the kidneys, the antecedent symptoms should be duly estimated, and the examination

directed to the existence of collections of matter in the pelvis and calices of the organ, or to their distention by urine from obstruction of the ureter, or to the presence of malignant disease of the kidney. Of these several states of disease, as well as of the passage of a calculus along the ureter, no correct diagnosis can be formed until the urine be tested, and the results considered with due reference to the quantity, specific gravity, appearances, deposits, and quality of this secretion; to the ability of retaining it, to the frequency of the calls to void it, and to the particular alterations of sensibility complained of in the regions of the kidneys, ureters, bladder, and urethra, as well as in the testes, abdomen, and lower extremities, and to the states of constitution and of vital power. In the course of renal disease associated with calculi, the symptoms are so varied, and manifest so numerous combinations, with the seat, duration, extension, and associations of morbid action, that descriptions applicable to all cases would be hopeless; but, by recollecting that irritation existing in one part of the urinary apparatus will extend to, and more or less affect the whole; that although the symptoms will be present chiefly in the situations just indicated, they may extend still farther; and that a correct examination of the urine will indicate with more or less accuracy the nature of the affection, especially when viewed in connexion with the local and constitutional symptoms, the difficulty of forming a diagnosis between the disorders which result from renal calculi and those which most nearly resemble them will altogether disappear. In this subject I must refer the reader to what I have stated respecting the inflammatory and organic diseases of KIDNEYS and URINARY BLADDER, and the complications which they present in practice.

173. iii. The *symptoms* indicating the *passage of a calculus from the kidney to the bladder* may be so slight, especially when the calculus is small and smooth, as to occasion but little inconvenience, and to excite no anxiety or even the attention; and it may remain long afterward in the bladder without the patient being aware of its presence. But if the renal calculus be large, or rough, more especially if it be an oxalate, its passage along the ureter is attended by the most excruciating suffering. The pain is seated more especially in the loins, generally of one side, extends from the course of the ureter and down the thigh, the cord to the testes; and is attended by retching, vomitings, and by intermitting colicky or abdominal pains. The patient is bent double, or to one side, rolls about, and is in the greatest agony. In the less severe cases there are rigors, nausea, restlessness, pain in the back, stretching in the course of the ureter to the bladder, thigh, and testicle, often with its retraction, coldness of the extremities, and prostration. The descent of the calculus commonly occupies from 12 to 24 or 36 hours. "The calculus may become impacted in the vesical orifice of the ureter; the flow of urine from the corresponding kidney may then be prevented; dilatation of the ureter, and distention of the tubular structure of the kidney will ensue, terminating in absorption of its secreting surface; but most of the usual symptoms of stone in the bladder will be absent."<sup>\*</sup>

\* M. CIVIALE classifies *uric acid gravel* under three varieties: 1. The passage of gravel spontaneously and without pain; 2. Nephritic colic with emissions of gravel;

174. iv. *The symptoms of a calculus in the bladder* are well known, and require at this place but few remarks. But in tracing back the history of these cases, and when inquiring into their existing states, the facts should not be overlooked, 1st, that stone in the bladder originates, in the great majority of cases, in a calculus formed in the kidney, which, having passed into the bladder, forms the nucleus of farther deposit and concretion in this organ; 2d, that the formation of the calculus in the kidney, and its passage thence along the ureter into the bladder, must have been attended by more or less ailment referable to these situations; 3d, that a calculus very rarely or never originates in the bladder without previous disease either of this viscus, or of the prostate gland, or of the urethra.

175. *The symptoms* chiefly characterizing the existence of a *concretion in the bladder* are frequent calls to micturate, pain at the end of the penis, hæmaturia, especially after exertion, and pain with or without hæmaturia on a jolting motion or succussion of the trunk. If these, however, be alone recognised, they may mislead the physician; for they may all be present, and yet a calculus may not be present in the bladder. Hence the necessity of inquiring into the history of the case, and of duly estimating the early symptoms. For some malignant growth may exist in the bladder and occasion all the symptoms just mentioned. A calculus in the vesical cavity generally falls behind the prostate, but it shifts according to the posture of the patient. In the earlier stages of vesical calculus, the viscus being yet healthy, a dull pain, with a sense of weight about the neck of the bladder, or uneasiness, extends to the hypogastric region, perineum, groins, or thighs. If the stone be smooth, the symptoms commence and advance so slightly and slowly as to excite but little attention and no anxiety; but sooner or later, either from the size of the calculus or the irritation produced by it, the features of the affection become manifest. The bladder is irritable and cannot contain its contents; the calls to micturate are more frequent; and the expulsion of the last drops is attended by pain, shooting along the perineum and penis, and centring in the glans. Sometimes when the urine is flowing in a full stream, it is suddenly stopped, as if by some body falling into and obstructing the orifice of the urethra. Exercise, sudden movements, and the jolting of a carriage occasion great suffering, and even a discharge of bloody urine, which in plethoric or other habits of body may be of considerable extent or continuance; as the disease continues, and the bladder becomes more affected, micturition becomes more and more frequent and distressing. Patients oft-

en grind their teeth with agony; and the last drops of urine are expelled with spasm of the bladder, which endures for some time. The urine and contents of the vesiculæ seminales are sometimes passed involuntarily, and increase the distress and exhaustion of the patient. There is occasionally priapism, with or without sexual desire.

176. I need not farther describe the symptoms of vesical calculus, but merely briefly advert to the importance of recognising some of the *complications* of this malady, and which may either precede it or follow it, more especially the latter. Of these the most important is disease of the kidney or kidneys. This may have preceded the vesical calculus, and been associated with, or caused by, the formation of the renal calculus which formed the nucleus for farther deposit and concretion when it passed into the bladder. But in this state of complication the renal disorder is generally slight, or even hardly exists when the calculus has reached the bladder. If, however, it be arrested in its course, more particularly at the vesical extremity of the ureter, the renal complication may be most severe and dangerous. After the calculus has been long in the bladder and superinduced much disease in this viscus, the interruptions in the way of urinary excretion, the extension of irritation along the ureters, and other circumstances, often develop serious disease, and even extensive disorganization of the kidneys. In some cases, also, the irritation of the bladder by a calculus may superinduce prolapsus ani in children, or even in older subjects, and hæmorrhoids in the latter class.

177. v. *Diagnosis*.—The symptoms described above (§ 174-6) generally lead to the important measure of ascertaining beyond a doubt the existence of a stone in the bladder, viz., to *sound-ing*. The circumstance of malignant disease of the bladder being often attended by most of the symptoms characterizing vesical calculus; and the fact of this operation, which is so requisite in the latter malady, being often most injurious in the former, should lead us to pause before it is resorted to, and the states and appearances of the urine very minutely examined. In cases of vesical calculus the urine generally contains more or less of the ordinary sedimentary and organic matter, and the blood discharged with the urine is generally in smaller quantity than in malignant growths in the kidneys or bladder.

178. In calculus, hæmaturia generally follows upon some unwonted exertion. In malignant growths in the bladder or kidneys, the tendency to nausea and vomitings is greater, and there are more marked appearances of cachexia and of anæmia than in calculus. In some cases, also, a careful examination of the abdomen will lead to the detection of tumours, if there be malignant disease of the kidneys, especially after the bowels have been freely evacuated. Malignant disease of the kidneys or bladder, or fungoid growths in the latter, especially when far advanced, is characterized by discharges of urine with much blood, intermixed with which the cells constituting malignant disease may be detected by the aid of the microscope. Dr. OWEN REES reposes much confidence in the evidence furnished by these cells of the existence of such disease. He describes them to be "of variable size, the smaller being about four times the diameter of a blood-corpuscle, the larger twice that size, or even of

3. Nephritic colics without expulsion of gravel. The disease in those, as well as phosphatic gravel, cystine, and oxalate of lime, may go on in spite of medical treatment, when the difficulty may arise from some morbid state, which paralyzes the efforts of nature and art. For example, the gravel may not be able to make its escape, because it is retained in the kidneys or ureters, or in the bladder, where it may be retained, 1st. By a spasmodic contraction of the urethra or neck of the bladder; or, 2d. By one or more contractions in the deep-seated portion of the urethra; or, 3d. By a tumefaction or other disease of the prostate; or, lastly, by a paralysis of the bladder. M. CIVALE rejects entirely the prevailing doctrines respecting the influence of *nitrogenized* food in the production of gravel and stone, and repudiates all attempts at cure by *chemical remedies*, either internal or external, and especially by *alkaline remedies*. He, however, attaches great importance to the influence of age, sex, climate, and food, in the production of calculous affections.]

greater diameter. They are colourless and more transparent than the white corpuscles of the blood, and contain within them nuclei of varying size. These nuclei differ in number in each cell. Sometimes only one is present; sometimes four or five. Though there would appear a general tendency on the part of these bodies to assume the circular form, they are for the most part of irregular outline. Sometimes a mass of them may be seen agglutinated together, and then they are more or less square, or they may approach to the hexagonal form." Dr. O. REES states that he has never seen corpuscles like these in the urine, except in cases of malignant disease. Where these are found, he contends that the sound should never be introduced into the bladder, as it may be followed by excessive, or even fatal hæmorrhage, a case of this latter issue having fallen under his observation.

179. VIII. TREATMENT OF URINARY CONCRETIONS.—i. *Of Calculi in the Kidneys.*—When the symptoms indicating the existence of calculi in the kidney are severe, and the patient is strong or plethoric, or not reduced by hæmorrhages from these organs, then cupping over the loins, followed by warm baths and fomentations, will afford relief. The preparations of soap and extract of henbane, or of belladonna, may be prescribed internally, while mucilaginous or demulcent fluids, containing the carbonates of the alkalies with narcotics, should be freely administered. The bowels ought to be kept open by means of olive oil in frequent doses, or by the citrate of potash taken freely, in a state of effervescence, and with the alkali in excess. If hæmaturia be excessive, the acetate of lead with opium, or the spirits of turpentine, cautiously exhibited in small doses, epithems of the same being applied to the loins, will be found of service; or the gallic or tannic acids, &c., may be prescribed. In cases where it might be injurious to abstract blood, dry-cupping over the loins may be employed.

180. Having removed the more severe symptoms by these or similar means, a course of medicines calculated to prevent the formation of uric acid and urates, and to lessen their irritating effects, should be entered upon. But such a course will prove ineffective if the diet and regimen of the patient be neglected. The citrate and bicarbonate of potash, the citrate or carbonate of magnesia, and other antacids, conjoined with tonics, will generally be of service, both in preventing acidity and promoting digestion, and in depurating the blood. A vegetable and farinaceous diet should be adopted, the quantity of flesh-meats much diminished, and the white kinds of fish, boiled only, and with no other sauce than a squeeze of lemon, should replace a large portion of the other articles of animal food usually taken. The beverage of the patient may consist of any of the mineral waters in which the alkalies most abound; or distilled water may be drunk, when effervescing with the bicarbonate of potash and citric acid or lemon juice, or with the addition of either the citrate of potash or citrate of magnesia, according to the state of the bowels. When the bladder is irritable, the several kinds of soap, with henbane or with opium, may be taken at bedtime. In all these cases, I have seen much benefit result from the use of distilled\* water, as the

vehicle for depurants of the blood, and for the important domestic purposes of making tea, coffee, &c. The due promotion of the functions of the skin, in this class of patients, and the use of the warm bath, of flannels next to the skin, should not be overlooked.

181. ii. *The treatment of the passage of renal calculi* is often of urgent importance, owing rather to the agony produced than to the danger incurred. The sufferings of the patient are generally increased in these cases by constant or frequent retchings, which also require to be assuaged. A warm bath should be immediately ordered, and before it is ready, or while it is being prepared, from 40 to 50 minims of laudanum, or a lesser dose of BATTLEY'S solution of opium, may be given. If the symptoms be still severe, and the vomitings continue after the patient's removal from the warm bath, creasote may be prescribed with demulcents, or other substances; or hydrocyanic acid, or chloroform, may also be added to these. The warm bath may be repeated, or warm fomentations be employed, and emollient and mucilaginous fluids, containing alkaline carbonates and anodynes, be freely taken. If the patient's sufferings be not very considerably relieved by these, the extract or tincture of belladonna may be added to the pills or mixtures already advised, and to the fomentations, which should be continued until complete relief is obtained.

182. During the passage of calculi from the kidneys, the state of the urine should be carefully ascertained, and the bowels satisfactorily evacuated, either by magnesia or the citrate of magnesia taken in demulcent vehicles, or by oleaginous enemata, administered in large quantity, and repeated as they may be required. After relief is obtained, the medical treatment advised for renal calculi should be persisted in for some time, conformably with the indications furnished by the appearances and deposits of the urine. The diet and regimen recommended above (§ 180) should be continued throughout, or modified according as the state of the patient and the alterations in the urine may suggest, due care being taken not to reduce the digestive and the assimilative functions, not to lower vital or constitutional power, and not to impair the secreting and depurating actions.

183 *The treatment of vesical calculi* differs but little from that advised. The avoidance of exertion or of sudden movements, &c., as advised for renal disease, strict attention to diet, and the adoption of the medical treatment recommended for the several kinds of urinary deposit, conformably with the kind existing in the urine, and for renal concretions, are also required for vesical calculi. In many cases, however, the irritation produced in the bladder, the consequent inflammation, hæmaturia, &c., and the complication of disease of the kidneys, of the prostate, &c., render the treatment most difficult, and its benefits often doubtful, however rationally conducted. It is unnecessary to add at this place to what I have already stated when describing the treatment of diseases of the URINARY BLADDER and of the KIDNEYS, and when noticing the indications of cure furnished by URINARY DEPOSITS. When a stone exists in the bladder and produces irritation of more or less manifest severity, the probability of that irritation being followed by the consequences just named, however judicious the medical treat-

\* Pure rain-water will answer equally well. We have often known great relief afforded by merely substituting this for the water usually drunk.]

ment may be, is very great; and hence the necessity of removing the stone by a surgical operation, unless the consecutive diseases or lesions—the superinduced complications, forbid its performance. As to this and other topics connected with the surgical treatment of vesical concretions, I must refer the reader to the very able surgical works enumerated in the subjoined BIBLIOGRAPHY and REFERENCES.

[We should, however, in this connexion, remember the remark of PROUT, that as healthy urine contains no free uncombined alkaline or acid ingredient, lithic agents, or, more properly, *lithon-lithics*, are to be sought for among a class of harmless and unirritating compounds, the elements of which are so associated as to act at the same time, with respect to calculous ingredients, both as alkalies and acids. The substances which approach the nearest to such are the solutions of the supercarbonated alkalies, containing a great excess of carbonic acid, and which may be used in two forms—1st, as natural mineral waters, as those of Saratoga, &c.; or, 2d, artificial soda or potash waters. If the calculus is of the *lithic acid* variety, from half a drachm to one drachm of bicarbonate of potash and as much tartarized soda may be dissolved in a pint bottle and taken twice a day with an equal quantity of soft or rain water; while, if the urine is alkaline and the concretions are of the phosphatic variety, the alkali may be omitted altogether, and the compound consist either of pure water impregnated with carbonic acid gas, or occasionally some acid, as the *nitric*, may be substituted for the alkali. *Lime-water* has been recommended for the *urates* by CHEVALLIER, on the ground of its forming a very soluble salt, *urate of lime*, with uric acid; and he also thinks it useful for phosphatic calculi, either by depriving them of a portion of the uric acid they contain, and thus rendering them less dense; by decomposing the ammoniacal salt which enters into the composition of some; or by acting on the animal matter which holds the molecules of these calculi together. The phosphate of soda and borax are also employed, on chemical grounds, as good solvents for lithic acid. On the whole, we have no good reason for believing that any of the agents recommended as true solvents for calculi exert any such effect in any considerable degree, but many of them, especially the alkalies, relieve the pain and irritation of the urinary organs, from their sedative influence upon the mucous surfaces, or from their effect on the digestive organs. Perhaps, also, the benefit which often results from their use may be in part owing to the fact that they are accompanied generally with the copious use of aqueous fluids. With regard to the reputed influence of lithonlithics when injected into the bladder, we must refer to the surgical works of BODIE, CHELIUS, VELPEAU, and GROSS.]

184. IX. DISEASED EXCRETION AND SUPPRESSION OF URINE.—The urine may be voided not only in the very different degrees of quantity, and in the states of chemical constitution described above as indications and important parts of disordered vital function and of local disease, but it also may be discharged with more or less effort and suffering on the part of the patient. It may, moreover, be retained in the bladder, owing either to paralysis and over-distention of the organ, or to mechanical obstacles at the neck or outlet of the viscus, or in some part of the urethra. The urine is also often either secreted in remarkably

small quantity, or suppressed altogether, owing to disease of the kidneys, the blood and nervous masses becoming poisoned by the arrest of the important depurating function of these organs, and by the resulting excrementitious plethora of the vascular system, and accumulation of urea, &c., which these organs eliminate from the blood as long as these functions continue. An altered or poisoned state of the blood may also arrest the functions of the kidneys.

185. i. *Difficult excretion of urine, urina difficilis excretio*, or *Dysuria* (from *δύς*, difficult, and *ουρον*, urine), is entirely symptomatic of disease affecting some part of the urinary apparatus, or some organ or part in the vicinity. It is generally characterized by heat and pain, as well as difficulty and delay, in procuring the discharge. *Dysuria* may depend upon the properties or chemical constitution of the urine, especially in irritable states of the urinary bladder and urethra; and in such cases, as well as in others where these properties are not present, it may be symptomatic of disease of the kidneys, especially of inflammatory and organic diseases. Most frequently, however, it is a symptom of the diseases of the urinary bladder and of the urethra, and of gravel and urinary concretions. It is not unfrequently present in diseases of the neck and body of the uterus, in the severe cases of dysmenorrhœa and leucorrhœa; in dysentery and inflammation of the rectum, and in cases of inflammatory hæmorrhoids.

186. ii. *Strangury, stranguria* (from *σπράγγειν*, to squeeze, and *ουρον*, urine), is a more severe degree of the preceding complaint, and is most frequently a symptom of diseases of the urinary organs, more particularly of over-distention of the bladder, of lesions of the neck of the organ and prostate gland, and of the urethra, and of urinary calculi and gravel. In dysuria the urine may flow in a full stream; but in strangury it is much interrupted, or passes in small quantities, or in drops, after great effort.

187. iii. *Ischuria* (from *ἰσχω*, I arrest, and *ουρον*, the urine) has usually implied an arrested discharge of urine; the arrest taking place either in the kidneys—*ischuria renalis*; *anuria* (WILLIS), renal ischuria; or in the bladder, from paralysis of the organ, or from some obstruction at its outlet—*ischuria vesicalis*, *I. vera*, *I. retentivis*, vesical ischuria; or in the urethra—*ischuria urethralis*, from stricture, phymosis, &c. Besides those symptomatic states of ischuria, or of retention and suppression of urine, other forms of retention arising from calculi, and from disease of, or tumours in, the uterus or vagina, &c., may be enumerated. This subject is more fully discussed in the article SYMPTOMATOLOGY (sec § 210–218); but there is one part of it, and that of the highest importance, which requires a more particular consideration, namely, *Ischuria Renalis*, *Anuria*, of Dr. WILLIS, or *Suppression of Urine*, the excretion not being eliminated by the kidneys, urine not being secreted.

188. iv. *Suppression of urine* is always a symptom of pre-existing disease, but of so many, and of so dangerous maladies, as to require a short notice at this place. It is very doubtful whether or no it ever is a primary or idiopathic malady, in the strict acceptation of the word; although it occasionally deserves this rank as much as some others which have been so denominated. It is often observed in the course of pestilential mala-

dies, more especially in the severer grades and advanced stage of *pestilential cholera*. It is also not infrequent in the *hæmagastic pestilence*. It sometimes occurs as a fatal, or at least a most dangerous symptom of exanthematous fevers, more particularly of *scarlet fever*. In these, and in other continued fevers, in which it is occasionally observed, suppression of urine has been either too often overlooked, or not viewed with due consideration. In all these maladies it may be either *partial* or *complete*. In either case, the consequences, as respects the blood, nervous system, and structures generally, may be readily inferred. It also frequently supervenes, either partially or completely, in cases of inflammation, acute or chronic, of the kidneys, and of organic lesions of those organs, most frequently of *granular disease*, or cachectic inflammation of the Malpighian bodies, but most generally in a partial or incomplete form. *Suppression* of urine is a more complete or rapidly dangerous or fatal form; often follows injuries and diseases of the spinal cord or its membranes, although *retention* is a more common result; and it is not an infrequent consequence of various modes of poisoning, owing either to inflammatory action or congestion thereby induced in the secreting structure of the kidneys, or to a paralysis of the ganglia and nerves supplying these organs.

189. *A. The symptoms* caused by *suppression of urine* vary with the circumstances of the case, and more especially with the slowness or rapidity with which suppression takes place, and with the disease of which it is a consequence.—*A.* When this condition proceeds from granular lesions, atrophy, or other organic change in the kidneys, it is generally slow in its progress, and it is often not observed, or rather the diminished excretion of urine has been of considerable continuance, before it has attracted notice; the urine being not only very scanty, but also very much altered from the healthy state, as shown in the articles on *DROPSY* and *diseases of the kidneys*, and in the preceding sections. In these cases, with the slow progress of diminution of urine and of the solid constituents of this excretion, the cutaneous and pulmonary exhalations are sometimes increased, and their odour is most offensive; effusion often gradually supervenes in the cellular tissue and in the shut cavities, sometimes with evidence of a chronic inflammatory irritation of the serous membranes investing these cavities; and ultimately the dangerous and commonly fatal phenomena rapidly supervening upon the acute form of suppression, or of that occurring in the advanced stage of malignant maladies, make their appearance.

190. *B. When suppression of urine* takes place more rapidly, the disease is then characterized by many of the symptoms of continued fever. There are pains in the back, but chiefly in the loins and in the lower extremities, with nausea and vomiting, and often with a sense of weight or of uneasiness if actual pain or severe aching in these situations be not felt. In some cases vomitings are urgent, and the fluid thrown up is generally watery, and in a few instances has an urinous odour. The pulse is rapid, full, and distended; perspiration, at first scanty, becomes more copious, in some instances abundantly so, and ultimately it has often an offensive urinous odour. After a time varying from three to five days, or occasionally longer, effusion takes place in the

cellular tissue and shut cavities, with a tumid or bloated state of the countenance, especially about the eyes. In cases of somewhat longer duration, œdema of the face and extremities comes on and advances more slowly; but as these changes advance, sopor supervenes and passes into profound coma, and sometimes into coma terminating in convulsions, especially in children. Generally long before these symptoms appear, either the extreme diminution of the quantity of urine, or its entire suppression, has been recognised by the physician, if he have been consulted so early; and when the catheter is introduced to determine correctly the existence of urine in the bladder—the presence or absence of which, however, is generally evinced by the state of the hypogastric region—nothing beyond a very minute portion of a thick, muddy, or mucous and offensive urine is withdrawn. This form of suppression of urine, whether occurring primarily, as I believe I have seen it in a very few instances, or in the early progress of other diseases, or in the gouty diathesis, or as a consequence of misplaced or suppressed gout, may be ascribed to a state of congestive inflammation of the secreting structure of the kidneys, in which the organic nervous or vital influence of these organs is rapidly exhausted or suppressed.

191. *C. When suppression of urine, or anuria*, occurs in the advanced progress of malignant or pestilential maladies, the duration of the symptoms more especially appertaining to it is much shorter, and the course of the malady in which it appears is very much hastened by it to a fatal issue. The changes usually consequent upon the anuria often do not take place until shortly before death; the earlier effects of the lost function of the kidneys being chiefly an aggravation of all the symptoms and diagnostic characters of the malady in which it occurs. It is very remarkable in the case of malignant scarlet fever and pestilential cholera and yellow fever. Very soon, however, generally in a day or two, and often after a few hours, as in pestilential cholera, sinking, sopor, convulsions or coma, &c., occur and terminate life; œdema of the face and extremities, effusion within the cranium, &c., also taking place shortly before death in scarlet fever, and sometimes in the hæmagastic pestilence. In pestilential cholera, the watery discharges from the stomach and bowels prevent the excrementitial plethora of the vascular system from taking place, that occasions the coma, effusion, &c., which are usually the results of anuria; when it supervenes in the course of other acute maladies.

192. *D. Drs. WILLIS and SCHÖNLIN* described a form of anuria which sometimes occurs in weak and cachectic children, and which I have observed also in the children of the poor living in cold, damp, or low situations. In these the digestive mucous surface is much disordered; the secretions and excretions are acid and offensive, and the cutaneous surface is affected by various eruptions, chiefly erythematous, vesicular, and pustular. The urine is scanty, is sometimes more or less albuminous, is voided in drops after short intervals, with pain and difficulty, and is ultimately quite suppressed. The pulse is at first quick and weak, but it gradually becomes slower, as sopor, coma, or convulsions supervene. These symptoms are usually preceded by constipation, by œdema of the face and extremities, by vomitings and retchings, and are ultimately followed by

death. In some cases, especially when perspirations are abundant towards the close of the disease, this excretion has a urinous or an acid and offensive odour. The breath also often has a similar odour.

193. *E. In fatal cases of rapid or sudden suppression of urine, and when this event occurs in exanthematous and malignant diseases, the kidneys are found of a very dark colour, from the congestion of dark blood, or they present a livid or bluish-brown tint; or they are flabby, enlarged, and friable. These changes are most remarkable in the secreting structure, the tubuli being often filled with epithelial débris. In malignant scarlatina, suppression of urine presents appearances in the kidneys described when treating of SCARLET FEVER (see § 66). In the slower or more chronic cases, the appearances are altogether the same as those stated when treating of granular or cachectic inflammation of the KIDNEYS (§ 99, *et seq.*). The changes in the cases of suppression of urine in children, which I have had an opportunity of observing, were similar to those which I have mentioned under the head of scarlet fever. Indeed, in some of these cases I had viewed the disease as an abortion or latent state of scarlet fever, in which the affection of the throat and skin had not appeared, as I have described it in that article. (See § 26, *et seq.*)*

194. It is manifest that the fatal result, in cases of suppression of urine, arises from two pathological conditions: 1st, from the excrementitious plethora of the vascular system, the superabundance of the watery element causing effusion on the brain, its membranes, cellular tissues, and shut cavities; and, 2d, from the accumulation of urea, uric acid, &c., in the blood, which poisons the nervous masses and vital structures, thereby aiding the destructive effects of effusion, or even proving fatal independently of these effects.

195. *F. The treatment of suppression of urine is rarely encouraging, owing to its want of success, and the fatal results which surely follow the very general failure of it. Yet treatment should not be neglected, as it may succeed in a few or rare cases. Besides, hopes of success may be reasonably entertained, if the suppression be incomplete. In cases occurring in acute, exanthematous, malignant, or pestilential maladies, the small quantity of urine passed before complete suppression takes place may or may not be albuminous, and of diminished specific gravity; it is sometimes thus altered in scarlet fever, but it is not, as far as I have seen, in other malignant diseases. In these, if the state of the pulse and other circumstances allow, the patient should be cupped on the loins, and the operation repeated, to an extent according to the features of the case and the effect produced. If the loss of blood cannot be hazarded, dry-cupping should be adopted; and the patient, under all circumstances, should be placed in a warm bath, rendered more or less alkaline by the addition of the carbonate of potash or soda. After leaving the bath, a turpentine epithem or embrocation may be placed over the loins, or an embrocation consisting of equal parts of the compound turpentine and camphor liniments should be applied in the same situation, or over the abdomen. The bowels must be kept freely open by the more diuretic purgatives, and by terebinthinate or other enemata; and diuretics should be taken, variously combined, or conjoined with sedatives or anodynes, according*

to circumstances, more especially the preparations of taraxacum, of digitalis, of scoparium, &c.; the carbonates, the nitrates, the acetates, the tartrates, the bitartrates, and the biborates of the fixed alkalis, in large doses, or in as large as the stomach will tolerate. If these fail, the following may be tried as a *dernier ressort*:

No. 364. R Olei Terebinthinae, ʒij.; Spirit. Ætheris Nitrici, ʒss.; Spirit. Juniperi Comp., ʒss.; Olei Cajuputi, ℥xx.; Potassæ Nitratis, ʒi.; Pulv. Tragacanth. Comp., ʒiij.; Pulv. Glycyrrhæ, ʒss.; tere bene et adde Syrupi Rosæ, Syrupi Tolutani, aa, ʒss.; Aquæ destillatæ ad ʒviij. Misce bene. Sit mist. cuius capiat Cochle. ij. larga, 3tiss, 4tis, vel 6tis horis, prius agitata phiala.

If the vomiting preclude the retention of these medicines, a very small quantity ( $\frac{1}{2}$  or i minim) of creasote may be added, or from three to six drops of tinctura opii, to each dose, or both may be given in addition, and the terebinthinated embrocation applied over the epigastrium. When suppression of urine follows chronic disease of the kidneys, complicated with dropsy, and more especially when it is associated also with organic disease of the heart, then little or no permanent benefit will be derived from any means of treatment; those just mentioned being the most appropriate, and sometimes affording temporary benefit.

- THE BIBLIOGRAPHY OF URINE, URINARY DISPOSITS, AND CONCRETIONS, especially of the Causes, Symptoms, and Treatment of Urinary Concretions, is the most extensive of any branch of Medical Literature. I have mentioned only a few of the best works and memoirs on these subjects; but those who desire to be farther informed will find numerous other references in *LOCQUET'S Literatura Medica Digesta*, articles *Calculus Urinarius* and *Urina*; in the *Repertorium* of *J. D. REUSS*, arts. *Calculus Urinarius*, vol. xii., p. 178-217, and *Urina*, vol. xv., p. 124-174; and in the *Appendix* to Mr. CROSSE's able and laborious work, referred to above. Most of the References I have adduced are, however, not contained in these works.
- [AM. BIBLIOG. AND RIEUR.—But very few monographs on the disorders of the urine and its deposits have yet appeared from the pens of American practitioners. The special works of *Prout*, *Bird*, *Marckwick*, *Willis*, *Rees*, *Griffith*, and other British writers on these subjects, are familiar to American practitioners; and in no part of the world, it is believed, are these affections treated more judiciously and scientifically than by the physicians of the United States, especially those more recently educated. All the recent improvements, both of a medical and surgical kind, have been here introduced; and lithotripsy has been practised more generally, it is believed, than in any other country, except France. In no other nation has the operation of lithotomy been generally more successful than in this, and in no other can any surgeon boast of a greater number of successful cases than our own *Dudley*.† Without any disparagement to other authors, it will be conceded that the work of Professor *S. D. Gross*, already referred to, on "*The Diseases, Injuries, and Malformations of the Urinary Bladder*," &c., is not surpassed by any other on the same subject in any language, as it embodies all that is positively known on these affections up to the present time. We take pride in referring American practitioners to this most enlightened work.—*S. D. Gross*, Elements of Path. Anat., 8vo. Phil., 1845; a Pract. URTICARIA.—SYNON.—*Urticaria* (from *Urtea*, a Nettle, the eruption resembling that caused by it), *Swediaur*, *Vogel*, *Willan*. *Febris Urticata*, *Vogel*. *Exanthema Urticatum*, *Borsieri*. *Scalatina Urticata*, *Sauvages*. *Purpura Urticata*, *Juncker*. *Uredo*, *Linnaeus*. *Essera*, *Heberden*. *Erysipelas Urticatum*, *Exanthesis Urticaria*, *Young*. *Epinyetis pruriginosa*, *Aspretudo*, *Auct.* *Exanthesis Urticaria*, *Good*. *Nesselsieber*, *Nesselsucht*, *Nesselausschlag*, *Germ.* *Fièvre Orliée*, *Fr.* *Ortiearia*, *Ital.* *Nettle-rash*.

CLASSIF.—ORDER GENUS (*Willan*), III.

CLASS, I. ORDER (*Author*).

1. DEFINIT.—*A febrile, non-infectious exanthema, characterized by an eruption of prominent wheals or spots, paler or redder, or even both, than the surrounding surface, rarely of long continuance, often recurring or becoming aggravated in fits, and always attended by a burning and stinging sensation.*

2. I. DESCRIPTION.—*Dr. Willan* has enumerated six species of *Urticaria*: 1st. *Urticaria febrilis*; 2d. *Urt. exanida*; 3d. *Urt. perstans*; 4th. *Urt. Conferta*, 5th. *Urt. Subcutanea*; and, 6th. *Urt. tuberosa*. These have been arranged by *M. Rayer* under two heads, according as their course is *acute* or *chronic*.

3. i. URTICARIA ACUTA.—The first variety under this head is the *Urt. febrilis*, which is generally caused by the ingestion of various articles, and frequently by shell-fish (see § 427, *et seq.*), and is to be imputed rather to a peculiar susceptibility or idiosyncrasy of the individual than to any noxious or poisonous quality in the article occasioning the eruption. Commonly in an hour or two after the ingestion of the article causing this affection the patient complains of a weight at the epigastrium, of nausea, sinking, or giddiness. These are followed by febrile symptoms, by heat of skin, and by the appearance of an eruption on the shoulders, breast, the loins, the inner sides of the arms, thighs, &c., generally consisting of reddish or whitish elevated spots, surrounded by bright crimson areolæ. The spots are generally irregular, but sometimes circular, varying in size, and elevated above the surrounding surface. When numerous in any part they are often confluent, the skin presenting a red tint, and being stiff and swollen (*Urt. Conferta*). The eruption is attended by distressing itching, pricking, or stinging, especially during the night; and sometimes the confluent variety is associated with erythematous blotches. When this form of the disease is caused by shell-fish, or by poisonous ingesta (§ 427, 434), the eruption is sometimes preceded or attended by vomiting or purging, or by both; and spasms, sensations of choking or suffocation, convulsions, sinkings, &c., have even supervened, and in rare instances terminated fatally. In the slighter cases of urticaria, caused by the ingesta, the white itching elevations of the skin are not observed, a simple efflorescence, resembling scarlatina, and belonging rather to erythema than to urticaria, being the characteristic symptom. After twenty-four, thirty-six, or forty hours the eruption usually declines, and soon afterward leaves only slight traces on the skin, which are effaced in a few days.

4. Febrile urticaria sometimes appears without any appreciable cause, except teething in chil-

dren, and intense moral emotions in adults. The symptoms are nearly the same as those caused by the ingesta, excepting that vomiting and purging are not observed, that the febrile symptoms continue longer, usually a week or longer, and that the eruption is less general, but appears and disappears in almost all parts of the surface, preceded by slight febrile symptoms. The patient can often excite spots of urticaria by friction, but these generally disappear in a few hours. In some instances the rash continues for two or three weeks (*Urticaria perstans*, WILLAN), and is attended by anorexia, functional disorders of the digestive organs, febrile symptoms, general depression, malaise, &c. The eruption usually declines imperceptibly, but it often returns with itching in different parts, and at last disappears. When urticaria has been severe, or has continued long, a slight desquamation generally follows.

5. URTICARIA CHRONICA.—Chronic urticaria often lasts for months. M. RAYER states that he has known it to continue for several years. This form of the disease is most frequent in females, and in persons with a delicate or sensitive skin. Although most common in those who complain of disorder of the digestive functions, yet it sometimes occurs in persons who are otherwise in good health. The eruption appears at irregular intervals, sometimes in one place, at other times in another (*Urt. crumida*, WILLAN), without fever, and often for a few hours only. The patches are generally irregular, and closely resemble the wheals produced by flagellation. They have no erythematous areolæ, and are attended only by severe pruritus. In some cases, instead of itching, a stinging or pricking sensation under the eruption is experienced (*Urt. Subcutanea*, WILLAN). In these the eruption is scanty, consisting of a few red points, but little elevated above the surface, and a small number of spots, that appear at very remote intervals. M. RAYER considers this form of urticaria to be very uncommon, and to be caused by violent moral emotions.

6. A severer variety of nettle-rash sometimes appears (*Urt. tuberosa*, WILLAN). It consists not merely in slightly prominent elevations, but in true tuberosities of various sizes, which are hard, deep-seated, extending to the subjacent cellular tissue, attended by slight ecchymosis, and by a tense and sore state of the limbs. These tuberosities generally appear in the evening or at night, with itching and stinging, and disappear before morning, leaving the patient weak, restless, and depressed. They occur more particularly on the loins and extremities, but they may come out over the whole of the body, causing swelling of the neck, limbs, and even the face; and are attended by various symptoms, as dyspnoea, irregular action of the heart, &c. They are usually developed with febrile action, and subside with the remission of the fever, reappearing with its accession (*Febris intermittens Urticata*, FRANK).

7. The varieties of chronic urticaria are very irregular in their courses. They sometimes disappear for several days, and reappear with or without an appreciable cause, after uncertain intervals. They often are not entirely removed for many months, in rare instances, not for some years; and either spontaneously or by a methodical plan of cure. TURNER, HEBERDEN, RAYER, and others, mention cases which continued many

years. I have recently attended a case with Mr. PETTIGREW, which resisted for above a year the most active treatment. When the eruption of these chronic forms of the disease is very severe, it is followed by a bran-like desquamation, constitutional symptoms of varied characters and severity being present, or recurring irregularly.

8. The associations of urticaria are common, and often important. With constitutional disturbance and disorder of the digestive organs, often depending upon an improper regimen and diet, urticaria is very generally associated. J. FRANK saw it complicated with quotidian and tertian agues, at Pavia, in May and June, 1794, and at Wilna, in March and April, 1812, in so many cases as to appear epidemical. In acute rheumatism the wheals of urticaria may appear, although not so frequently as the efflorescence of erythema or roseola. Nettle-rash is uncommon in connexion with diseases of the respiratory organs and passages. It is sometimes observed during various chronic visceral diseases, or cancerous and organic maladies, and after miscarriages occurring in nervous females. Urticaria may be complicated with other cutaneous eruptions, especially with erythema, or with roseola, or with lichen, and occasionally with impetigo. WICHMANN saw it associated with variola; HUFELAND with measles; RAYER with prurigo; and I have seen it in a case of jaundice, and in another of senile prurigo.

9. ii. THE CAUSES of urticaria are most frequently articles of diet, which, owing to their unwholesome or indigestible natures, or to idiosyncrasy or peculiarity of susceptibility, disorder the digestive and assimilating organs, and which, by passing into the circulation, excite more or less febrile action, and affect the capillary vessels of the skin. The ingestion of numerous articles is liable to induce urticaria, one article being more certain to occasion it than another, in those predisposed to it. Mussels, cockles, lobsters, crabs, shrimps; the roe of a fish; dried, smoked, and salt fish; dried, smoked, and preserved meats; mushrooms, nuts, and kernels of fruits (see art. POISONS, § 434, *et seq.*); cucumbers, and unripe or stale fruits; some kinds of honey, preserves; oatmeal, especially when long kept; certain medicines, as the balsams, resins, &c., and many other articles, according to particular idiosyncrasies, often occasion this eruption. I have seen it caused by fresh pork. Some persons are so susceptible as to become affected by it after slight friction. J. FRANK states that it is rare in Italy and frequent in Russia. This is to be attributed chiefly to the general use of olive oil in the former, and of animal oils and rancid substances, and dried meats and fish in the latter country. Nettle-rash is most common in summer, especially in women and persons of a nervous and sanguineous temperament; and is much more frequent in children, the young, and adults, than in the aged. Cold, or rather exposure to the air, appears to have considerable influence on the development of the wheals of urticaria, especially in respect of certain parts of the surface which are usually covered.

10. iii. DIAGNOSIS.—It should not be overlooked that the leaves of the *urtica urens*, *urtica dioica*, and *rhys toxicodendron*, the bite of the common bug, of the gnat, of the flea, and the hairs of certain caterpillars, may occasion an eruption of wheals, which, although evanescent, may at first,

if the cause be not inquired after, be mistaken for urticaria. The white and raised wheals surrounded by arcolæ, characterizing *urticaria*, differ from patches of *erythema* in these respects, and in stinging, pricking, and itching. *Erythema nodosum* is distinguished from *urticaria tuberosa* by the persistent nature of the former, and the intermitting course of the latter. *Roseola* cannot be confounded with the wheals of urticaria, as it presents red spots and patches, and not the dull white spots of urticaria, and is not attended by pruritus, and the pricking or stinging of this latter. The history and all the phenomena of the case will prevent the eruption from being, at any time during its course, mistaken for either *measles* or *scarlatina*. The papulæ of *Lichen Urticatus* are much more likely to be mistaken for urticaria, but they are less extensive and less prominent than the spots of urticaria; their colour is deeper, they are harder, and they never disappear spontaneously. The bites of insects already mentioned, although causing wheals and itchings, cannot be mistaken for any form of urticaria.

11. iv. PROGNOSIS.—This eruption has appeared as a salutary crisis in some instances of internal inflammatory disease, as remarked by Koch, Rayer, and others. While, on the other hand, the sudden disappearance of urticaria has been followed by the development or the increased activity of some internal disease. This has very probably been owing to the occurrence or progress of the latter causing the subsidence of the urticaria, rather than to the suppression of this eruption. No one of the forms of urticaria is attended by any danger, although the chronic states are often accompanied with much distress, and frequently resist the most appropriate treatment for a long time. The acute forms following the ingestion of poisonous articles, however severe, or even when fatal, cannot have the unfavourable results imputed to the eruption, inasmuch as these results proceed from other changes produced by these causes, the eruption being the least important of their effects.

12. v. TREATMENT.—When acute urticaria is produced by the ingestion of poisonous substances, or by articles which are injurious from the idiosyncrasy of the patient, emetics and the other means advised when treating of those poisonous articles which usually cause this eruption, are required (see *art. Poisons*, § 443, 450). After the stomach and bowels have been evacuated, liquor ammoniæ acetatis and nitrate of potash may be given in the camphor mixture, or in any demulcent infusion or decoction; or the hydrochlorate of ammonia in similar vehicles. Subsequently a warm bath may be resorted to and repeated, and the bowels kept open by means of cooling aperients. I have found olive oil, taken in frequent doses on the surface of mint water, and the application of this oil to the surface, either before or after a warm bath, of very great service. In full and robust habits of body, or in the young and strong, especially if visceral congestion be present, vascular depletions, in form and amount according to the circumstances of the case, should be early prescribed, a strict diet and regimen enforced, and in all cases a free state of the bowels, by means of cooling aperients, and emollient and demulcent decoctions, be preserved. The insomnia and restlessness so generally observed in the severer cases of this eruption require opiates, but they should

be conjoined with cooling diaphoretics and alkalies. I have found James's powder, or the antimonial powder, with the compound soap-pill, or the compound ipecacuanha powder, or a full dose of the carbonates of the fixed alkalies, or of magnesia, in a demulcent infusion, very successful in mitigating these symptoms, especially when either of these means has been resorted to after due evacuation of the bowels, and when taken early in the night, or rather in the evening. If febrile action be present, saline aperients, the acetate or citrate of potash or soda, with nitrate of potash, and spirits of nitric ether, in mint water, or in camphor mixture; or the citrate of magnesia, in doses sufficient to act on the bowels, will be found of great service.

13. The chronic states of urticaria are often most difficult to remove; and more especially as they are generally caused by errors in diet, and perpetuated by the use of articles which either disorder the digestive organs, or impair the depurating functions, or otherwise affect the circulating fluids, so as to irritate the capillary vessels of the skin. In these cases patients should adopt a restricted diet and regimen, and avoid spirituous, vinous, and fermented liquors, all kinds of shell-fish, and live entirely on farinaceous and vegetable food. I have seen the most obstinate cases, which had been treated by the too generally prescribed preparations of arsenic, iodine, &c., in large and improperly combined doses, yield to the use, chiefly or entirely, of farinaceous and vegetable diet, and distilled water; the secretions, excretions, and depurating functions generally being duly promoted by gentle cooling aperients, such as those mentioned above.

14. When the chronic states of urticaria assume a remittent or intermittent form, and if they do not readily yield to the means already advised, then the preparations of cinchona may be given with the carbonates of the fixed alkalies, or with the solution of the acetate of ammonia, or with the addition of the nitrate of potash; and warm alkaline baths, or vapour baths, be resorted to. External applications, especially those which are oily or greasy, should be avoided, excepting the olive and almond oils, to which the hydrocyanic acid may be added when the stinging and pricking are distressing. But even these should be washed off in a few hours, before they are made rancid by the air and the cutaneous exhalation.

UTERUS.—Some of the diseases of the uterine organs have been considered in the articles on the OVARIA and their diseases, on MENSTRUATION and its disorders, on DROPSIES of the ovarium, uterus, and Fallopian tubes, on LEUCORRHEEA, and on the diseases of the VAGINA and VULVA. Certain uterine maladies have also been fully described with reference to the puerperal states, when treating of PUERPERAL DISEASES. It now remains for me to view those morbid conditions of the uterus which are not noticed under other heads, and which appear to be of such importance as to require attention.

I. MORBID SENSIBILITY OF THE UTERUS.—SYNON.—*Hysteralgia* (from *ὑστέρα*, the womb, and *ἄλγος*, pain); *Metralgia*; *Uteralgia*; *Hysteradymia*. *Ὑστεραλγίης*, Hippocrates. *Neuralgie de l'Uterus*, *Métalgie*, Fr. *Der Gebärmutter-schmerz*, Ger. *Neuralgia of the uterus*. *Irritable uterus*.

CLASSIF.—I. CLASS, V. ORDER. (See Preface)

1. DEFIN.—Pain of the uterus, generally very severe, sometimes continued, at other times remittent or intermittent, particularly of the neck of the organ; occurring generally at a mature age, but seldom after the cessation of the catamenia; and not necessarily depending upon very manifest organic disease, although more or less inflammation and alteration of structure frequently exists.

2. Morbid sensibility of the uterus occurs, according to my observation, in two forms: 1st, in that which has been denominated *irritable uterus*, when indications of a slow, chronic, and often most protracted state of irritation, amounting in some cases to inflammation and its usual consequences, are present in the os and cervix uteri; and, 2d, in that which is more *neuralgic*, where these indications are not manifest, and where the nervous characters of intermission, &c., are most evident. An approximation of the characters of the one affection to those of the other may, however, be remarked in some instances.

3. i. IRRITABLE UTERUS, or *irritability of the uterus*, was first fully described by Dr. GOOCH. The notices taken of it in the works of RIEDLIN, POUTEAU, RIVIERUS, STOLL, and some others, are extremely unsatisfactory, and even calculated to mislead, it having generally been referred by them to rheumatism or gout affecting the womb.\* Since the publication of Dr. GOOCH's observations on this affection, Prof. DEWEES has directed attention to it; and the more recent writers on

the complaints of females have farther illustrated this subject, and shown its connexion with chronic inflammatory irritation.

4. Irritable uterus is seldom met with before twenty-three years of age, and as seldom after the menstrual epoch has ceased. Dr. GOOCH says that it is not attended by change of structure, and that it does not tend to such change, while Dr. DEWEES states that he has usually found some change about the neck of the uterus. In the cases of this affection for which I have been consulted, some have been unattended by any manifest alteration of structure, and others have been accompanied by indications of chronic inflammation of the cervix and os uteri. (§ 21, *et seq.*) In a case in my own family, no alteration could be detected for a very long time, but a change of structure subsequently became manifest, and assumed a malignant form.

5. ii. SYMPTOMS.—A. The constitutional symptoms are increased frequency of pulse on the slightest emotion or exertion; sometimes flushes, alternating with chilliness, previously to the exacerbations; pain in the lowest part of the abdomen along the brim of the pelvis, and often also in the loins, exacerbated by exercise, while it is diminished, although not removed, by perfect quietude in the horizontal posture; the pain sometimes recurs in paroxysms, even when the patient reclines, or is quite still, and is generally increased for a few days either before or immediately after menstruation; emaciation, paleness, weakness, and increased sensibility and irritability of the whole frame; an irregular state of the bowels, with difficult or painful micturition, and a pale, white tongue, particularly in the morning. Sometimes the pulse is soft, at other times firmer than usual; and although generally somewhat quickened, it is occasionally not above the usual frequency. The skin is commonly dry, and its temperature sometimes augmented, while the hands, legs, and feet, particularly the latter, are cold. The febrile exacerbations seldom terminate in perspiration. The patient occasionally complains of headache, which is often increased toward night. The appetite is usually impaired or capricious; and the bowels either are confined or much relaxed—most frequently the former, the latter more particularly when acted on by purgatives, which generally excite a paroxysm of pain. The urine is either sparing, high-coloured, and depositing a copious sediment; or it is pale, copious, and limpid, particularly when the affection is complicated with hysteria or neuralgic pains in other parts of the body: it is generally voided with difficulty and pain referred to the urethra; sometimes it is retained for a long period, and passed with great suffering.

6. B. The local Symptoms.—If the uterus be examined, it will be found exquisitely tender, particularly its orifice and neck, the former generally being neither misshapen nor indurated, although frequently somewhat swollen—a state in which the cervix often also participates. When the pain is excited by an examination, or by coitus, which is also very painful, it does not readily subside; and it is often induced by the patient seating herself suddenly upon a hard chair or bench, and usually by the sexual congress. In addition to these she frequently complains of a throbbing or fluttering sensation in the pelvic cavity and vagina. Walking, riding, or any exercise increases the symptoms, and causes severe

[\* Professor C. D. MEIGS expresses the opinion ("Females and their Diseases," Phil., 1843, p. 418) that what goes under the name of dysmenorrhœa is, for the most part, "rheumatic disorder." "The uterus becomes sensible on pressure with the finger; a pessary in contact with it produces heat and pain, while the touch reveals no change in the form, dimensions, or resistance of the cervix." Dr. M. thinks it "identical with what has been called irritable or neuralgic uterus;" states that it may continue for a long time without inducing any cognizable change in the parts. The *volatile tinct. guaiac*, so much extolled by DEWEES in dysmenorrhœa, proves efficacious, according to Professor M., "in virtue of its anti-rheumatic therapeutical force." The same able writer and teacher states that the gravid uterus is also the frequent subject of rheumatic attacks (*Loc. cit.*). Dr. M. also admits that "the womb, like any of the other tissues, may be the seat of a pure neuralgia or preternatural sensibility of the nerves of the tissues" (p. 437), which would be likely to be aggravated at the menstrual period.]

lancinating pains through the pelvic cavity, particularly in the course of the urethra, and about the centre of the sacrum: as these subside, a dull, diffused pain is felt in the same direction. Leucorrhœa frequently accompanies this affection, and often becomes abundant, the discharge varying from a thin, transparent, and inodorous matter to a thick, muco-purulent, and offensive fluid. There is often increased heat of the vagina. The uterus is occasionally found lower in the vagina than natural, and its neck is generally shortened and enlarged, and sensible to the touch. Pain is felt immediately behind the mons veneris and anterior part of the brim of the pelvis. The catamenia are at first but little affected in this complaint, but they ultimately become more and more scanty, while the sufferings of the patient are generally increased at their accession. They often prematurely cease, the patient being reduced by the protracted disease and by the confinement.

7. ii. *NEURALGIA UTERI*, or *uterine neuralgia*, has been considered a distinct disorder by some writers, and a modification of irritable uterus by others. (See *NEURALGIC DISORDERS*, § 43.) In this form of altered sensibility of the uterus, the pain is most exquisite, is generally referred to the body of the organ, does not continue for a very long time, and subsides entirely, or nearly entirely. It is altogether paroxysmal, and sometimes almost periodic. The general or constitutional symptoms are less evident, or altogether absent in this affection; but the debility and exhaustion may be greater. Examination per vaginam does not excite the pain in the intervals, although it may aggravate it in the paroxysm; and neither heat, nor leucorrhœal discharge, is usually present. This form of complaint is not commonly—or it is rarely—induced or aggravated by the causes which occasion or increase the sufferings in irritable uterus. The chief features of the neuralgic disorder are the extreme violence of pain during the paroxysm, and the complete or nearly complete subsidence of it during the intervals. Cases, however, occur in which the symptoms of the one form of disorder appear to lapse into those of the other.

8. *C.* The *diagnosis* of morbid sensibility of the uterus is manifest in the severity of the pain, and in the localization of it in the *cervix* and *os uteri*, especially of the *irritable form* of disorder, these parts evincing the utmost tenderness on examination, and the existence of great irritation, and ultimately of chronic inflammation and its consequences; namely, excoriation, leucorrhœal discharge, &c. The *neuralgic form* of disorder, as well as the irritable form, is unattended by any manifest change of the body of the womb, the symptoms of metritis or inflammation of the body of the uterus (§ 53, *et seq.*) also being absent. Although both affections are independent of displacement of the uterus, yet they may be accompanied with displacements in one or other form. They cannot be mistaken for dysmenorrhœa or painful menstruation, for they may be present during the intervals between the menstrual periods, although they may be aggravated by the accession of these periods. On vaginal examination of cases of these complaints, the uterus is usually found in its natural position, excepting that it is sometimes situated lower down in the pelvis, or otherwise more or less displaced. In recent cases it is free from organic change, be-

yond slight tumefaction or fulness, and occasionally softness of its mouth and neck; but in protracted cases, the changes produced by continued irritation and consecutive chronic inflammation usually supervene.

9. *D.* The *prognosis* of the above states of morbid sensibility of the uterus is favourable as regards the life of the patient, although it is not so favourable as respects a quick recovery. It may, if the causes continue to operate, be followed, after some years, by organic change, or even by malignant disease of the os and cervix uteri. While most of these cases will recover, if judiciously treated, some can only be relieved, and others may continue to suffer for many years, especially if the secret habits or vices in which the malady has originated be persisted in. The issue of these cases will depend much on the causes inducing them, on their recurrence, and on the physical and moral conditions of the patient.

[*Idiopathie uterine neuralgia* is, no doubt, often mistaken for what has been called by VALLEIX, *utero-lumbar neuralgia*. MALGAIGNE has also called attention to this affection, as well as MITCHELL, BEAU, and others. The former writer regards it as a variety of the *lumbo-abdominal neuralgia*, consisting essentially in an irritation of the lumbar nerves, the irritation usually concentrating itself on the cervix uteri. If the neuralgia is confined to one side of the lumbar region, the pain in the neck of the uterus is also confined to one side, and when it exists on both sides of the vertebræ, the pain in the cervix is more strongly marked on the side in which the neuralgia is most intense. This affection has been called by some *hystericalgia*, *rheumatism of the womb*, &c.; but it is simply utero-lumbar neuralgia. It is generally accompanied with leucorrhœa, or a discharge of mucus from the vagina. The prominent local symptoms of this disease, then, are pain in the uterus and over the lumbar region, increased by pressure; uterine sensibility, sensibly augmented by a digital examination, sexual intercourse, or the introduction of a speculum; also a discharge of mucus, &c. The diagnostic signs are sufficiently clear, viz., pain on pressing the lumbar vertebræ and the cervix uteri. The prognosis is favourable, provided the disease be recognised and the proper treatment carried out. The treatment consists mainly in powerful revulsives to the spine and cauterization of the cervix uteri. VALLEIX recommends a succession of blisters over the lumbar and sacral region, and also the actual cautery to the cervix. MALGAIGNE prefers scarifications of the neck of the uterus. MITCHELL, of Dublin, relies on the red-hot iron to the spine. A nitric acid issue on the side of the lumbar vertebræ has been found also very successful, and it is not likely to cause strangury, so often the result of the application of blisters to this region. If this affection is characterized by periodicity, quinine and other anti-periodics will be useful, and indeed will often effect a cure without local remedies.]

10. *E. Causes.*—*a.* The *predisposing causes* of these states of morbid sensibility of the uterus are constitutional sensibility and irritability, the nervous and irritable temperaments, the impulsive and susceptible disposition, a spare habit of body, previous liability to painful, difficult, or scanty menstruation, repeated abortions, and masturbation.—*b.* The *exciting causes* are not accu-

rately ascertained; but they appear to consist chiefly of fatigue, exertion, prolonged walks, or dancing or standing too long, and falls on the hips or back, or succussions of the body, particularly when the uterus is susceptible, or during the catamenia. Riding on horseback or in a carriage, especially if the road be rough, and during the menstrual period, or without duly evacuating the bladder; the use of cold or astringent lotions or injections to stop a profuse lochia or leucorrhœa; exposure to malaria, &c.; sitting on damp or cold stones, earth or iron seats, venereal excesses, and self-pollutions; neglected or protracted leucorrhœa.

11. *F.* The nature of *irritable uterus* was supposed by Dr. GOOCH to be similar to that of painful menstruation, the former being permanent, the latter recurring with the periodic discharge. He farther inferred that it is not inflammatory, because it does not terminate in change of structure; but it may, and often does, terminate in such change. He states that, after repeated examinations, nothing is discovered excepting exquisite tenderness and slight swelling, or rather tension of the cervix and os uteri. He farther supposes that the fact of many cases, after having lasted for years, terminating in entire recovery, is a sufficient proof that it is a disease of function only. Dr. DEWEES contends that it consists of a chronic inflammation, which he conceives may exist in some instances for an almost indefinite period without any very manifest derangement of structure; and he states besides that he has generally detected in this affection increased heat, and tumefaction as well as pain, which he views with justice as characteristic of chronic inflammation. M. GENEST nearly adopts the views of Dr. GOOCH, which, however, are much more applicable to the nature of neuralgia of the uterus than to the irritable form in which morbid sensibility of the os and cervix uteri most frequently occurs in practice. (See NEURALGIC AFFECTIONS, § 43, 44.)

12. My experience, derived from many cases in which my opinion has been requested in consultation, leads me to conclude that the two forms of morbid sensibility of the uterus are characterized by very different pathological conditions: 1st. that *neuralgia* of the uterus is an affection of the nerves of this organ, induced by depressing and exhausting causes, and is altogether independent of inflammatory action and organic change, although it may be associated with one or other of the several displacements and organic lesions of the womb about to be noticed; 2d, that *irritability* of the uterus is caused by irritation of the os and cervix uteri, this irritation being attended by exquisite morbid sensibility and tenderness, and by some degree of inflammatory action; that the irritation superinduces chronic inflammation of these parts, which may be protracted for a very long period, before it is followed by excoriations, by a morbid secretion and discharge from the excoriated surfaces, and from the irritated mucous glands in these situations, and ultimately by granulations, ulcerations, and even more serious organic change. According to this view, the greatest number of the cases formerly termed irritable uterus, or which had this term appropriately applied to them at an early stage only, were actually instances of irritation followed by chronic inflammation of the os and cervix uteri and its consequences. The writings

of Dr. HENRY BENNET have fully demonstrated the existence of these lesions, which, although denied by Dr. ROBERT LEE and some others, have been very often observed by Dr. SIMPSON, Dr. TYLER SMITH, Dr. West, Dr. WHITEHEAD, of Manchester, M. CHOMEL, and numerous continental writers, and by myself. The imperfect manner in which affections of the os and cervix uteri were observed when Dr. GOOCH wrote, prevented the true state of these parts from being duly recognised and estimated; and yet his admission of the existence of tenderness, fulness, tension, &c., in this situation, is a sufficient proof of the presence of inflammatory irritation, or of irritation usually passing into inflammation. (See *Inflammation of the Os and Cervix Uteri*, § 21, *et seq.*) When writing upon this subject in 1829, I remarked that, if morbid sensibility of the os and cervix uteri exist for some time, it often induces, or is attended by, an alteration of the circulation in these parts, by swelling and tension, by great tenderness, and by increased secretion from their surfaces—the augmented secretion generally tending to prevent the disorganizing effects of inflammatory irritation or action from taking place.\*

[\* We are inclined to believe that the pure "*irritable uterus*" very seldom occurs in practice; for however uncomplicated it may be in the commencement, by the time the physician is called in more or less engorgement or inflammation has ensued from the irritation set up. At least such has happened in nearly every case that has come under our observation: so that the definition of the disease by Dr. GOOCH, who first called attention to it, will not hold true, viz., "a painful and tender state of the uterus, neither attended by nor tending to produce change in its structure." Dr. DEWEES has given a very accurate account of this affection ("*A Treatise on the Diseases of Females*," p. 306. Phil., 1833), from which Dr. COPLAND has very freely drawn in his description, both of the general and local symptoms, as well as the diagnosis and treatment. According to our countryman (Dr. D.), the irritable uterus may be distinguished from a neuralgic condition of this part by the following signs: In *neuralgia of the uterus* there is an entire absence of the general or constitutional symptoms attending irritable uterus, especially the evening febrile movement; there is seldom a vaginal or leucorrhœal discharge; there is no preternatural heat in the vagina, nor is the uterus so sensible to the touch unless examined during the painful continuance of the paroxysm, and then, perhaps, it is more exquisitely sensible than it is in the pure irritable uterus. In *neuralgia*, moreover, the pain is less constant, but is more violent during the paroxysms, which generally observe periodicity. In *neuralgia*, a paroxysm may be suddenly induced by passions or emotions of the mind, which is never the case in the irritable uterus, though the latter is susceptible of great and occasional augmentation of pain, through the medium of the circulation, by errors in diet or improper exposure.

Dr. DEWEES also calls attention to the fact that irritable uterus is very apt to be confounded with prolapsus uteri, inasmuch "as the local symptoms of the latter are a miniature representation of the former," and as, in the former, the womb is certain to descend more or less, and hence is supposed to be the cause of all the difficulty. If a pessary be employed under such circumstances, the symptoms will necessarily be aggravated, and the ease rendered still more difficult.

By way of diagnosis, the mode of conducting an examination is all-important. The patient is to be placed upon her back, with the knees drawn up, the parts well lubricated; then passing the finger gently into the vagina, seek for the cervix uteri; and when found, direct the attention of the patient to the degree of sensation produced by touching it, as well as the body of the uterus and the sides of the vagina. Inquire if there be any extraordinary sensibility in either of these parts, and if so, in which part it resides. If there be tenderness, the use of a pessary or any mechanical means for supporting the uterus is out of the question.

The irritable uterus has also been confounded with dysmenorrhœa and carcinoma of this organ, but it may readily be distinguished from the former by the circumstance that in dysmenorrhœa pain is only felt during the menstrual discharge, while the irritable uterus is not nec-

13. iii. TREATMENT.—Very different means are requisite for these two forms of morbid sensibility of the uterus. It should not be overlooked that the one is unconnected with inflammatory action, is purely nervous, and is sudden in its accession and in its subsidence, while the other is more or less inflammatory either originally, or consecutively upon irritation, the morbid action, owing to the organization and sympathies of the parts affected, being more or less modified in character, and prolonged in duration. The circumstance of the os and cervix uteri being possessed of sensibility only inferior to that of the clitoris,\* their erectile organization, and their abundant supply of mucous follicles, often render them exquisitely tender and painful when inflamed, or even when they are the seats of irritation, and enable them to furnish an abundant secretion tending to resolve or to diminish inflammatory action, and to prevent the usual consequences of this action. Notwithstanding the advantages these parts derive from their organization, vital powers, and free discharge from their surfaces, when irritated, inflamed, or otherwise affected, inflammatory action, when once developed in them, is the more disposed to be protracted, but it is, from these circumstances, much less liable to consecutive alterations of structure; the chief organic lesions which occur being superficial exoriations, granulations, and ulcerations, with a more or less abundant leucorrhœal discharge. These alterations are the more likely to take place when the uterus falls low in the pelvis, when the morbid secretion accumulates, or is retained, in the vagi-

essarily attended by dysmenorrhœa, nor is the latter usually attended by this irritable condition of the uterus. A digital examination will readily distinguish irritable uterus from carcinoma uteri by attending to the marks laid down by our author.

With regard to the pathology, we are disposed to coincide with Dr. DREWES in the opinion that there is in this disease more or less inflammation of a sub-acute kind of all the tissues of the neck of the uterus, and perhaps the body also. Heat, swelling, and pain to a greater or less degree, we have always found present in this disease; and in a case now under treatment, of four years' standing, there is a swollen, tender condition of the cervix uteri, with slight ulceration. In another chronic case, which came under my care recently, there was considerable enlargement and ulceration of the neck of the womb. The pathology of Dr. DREWES appears to us, therefore, more accurate than that of GOOCH, who denies the presence of inflammation in irritable uterus. The most frequent exciting cause of this affection, according to our experience, is repeated abortions occurring in females of a highly nervous, susceptible temperament, and delicate organization; although we have met with it, but less frequently, in those of robust habit and of a sanguine temperament.

The treatment of this affection is necessarily protracted, difficult, and uncertain, and the patience of both physician and patient is likely to be exhausted before a cure is effected. Our water-cure (?) establishments abound with such cases, where they are generally treated with little discrimination and less success. Most of these cases are there treated for prolapsus; and in one institution, where such patients congregate in great number, we found it a common practice to subject the uterus daily to a pressure of some 20 lbs. of water to a square inch, introduced by a flexible tube attached to a hydrant! The treatment laid down by our author comprises all that is known, and may be summed up as follows: Absolute quiet in a recumbent posture, counter-irritants, anodyne injections and suppositories, laxatives and enemata, and tonics, with great attention to diet, &c.]

[\* M. JOHET maintains that the projecting portion of the cervix uteri is entirely deprived of nerves, and is, under all circumstances, insensible. Of course, he denies that it is ever the seat of pain. BOULLAUD goes still farther, and denies that the uterus receives any nerves whatever from the cerebro-spinal axis; this, however, is refuted by the positive observations of TIENEMANN, ROBERT LEE, MÜLLER, HERSCHFELD, BOULAN, and others.]

na, when vital or constitutional power is depressed or exhausted, and when the treatment pursued, and other circumstances, permit the air to have access to the irritated or inflamed parts. This form of altered sensibility of the uterus, however severe the pain characterizing it, being either identical with, or nearly allied to, irritation or chronic inflammation of the neck of the organ, the treatment appropriate to it will be necessarily the same as advised for that disease; the more painful symptoms being treated by such combinations or modifications of the remedies as have been found most beneficial in neuralgic affections, and in irritable and exhausted states of the system.

14. The *neuralgic affection*, or the *nervous form* of morbid sensibility of the womb, will, therefore, be chiefly considered at this place; the means, however, to be recommended for it will often be also required in the inflammatory states, and their consequences hereafter to be noticed, either conjointly with other constitutional and local remedies, or after recourse has been had to them. The indications of cure in this affection are, 1st, to subdue the sufferings of the patient; and, 2d, to prevent their recurrence, by restoring the constitutional powers, and healthy state of the uterus. Certain of the means calculated to fulfil the first will often aid the accomplishment of the second intention. The means to be employed with these views are the same as have been fully considered when discussing the *Treatment of NEURALGIC AFFECTIONS* (*see* § 80, *et seq.*); and they may be used as there recommended and prescribed.

15. In the more violent cases, the more energetic sedatives and narcotics may be applied *locally*, in the form either of suppositories, or of injections thrown into the vagina, or of enemata, the bulk of which should not exceed three or four ounces; sufficient care being taken not to prescribe too large a dose of the more sedative substances, especially in the injections, as the effects produced by them when thus exhibited may be as violent as when taken by the mouth. In a case which I attended with the late Dr. MOORE, very marked relief was procured by carrying, by means of a small piece of sponge, about half a drachm of the tincture of belladonna, in a female syringe, and pressing it out when it reached the os or cervix uteri. The paroxysm generally subsided after a very few minutes, and the more restorative means recommended in the article now referred to were afterward taken. These should be adapted to the peculiarities of the case, and more especially with due regard to the states of the vascular system, and to the causes and associations of the complaint. These last it is most important to recognise; for not only may the disorder be the result of depressing or exhausting causes, but it may be complicated with one or other of the several forms of displacement of the uterus, and even with tumours or other organic changes of the organ.

16. Besides the means now mentioned for the removal of the paroxysm, others may be tried; *chloroform* taken in doses of from twenty to thirty drops, by the mouth, or injected into the vagina, in the same or somewhat larger quantity; or suppositories, in which the extract of *belladonna* forms an ingredient, may be introduced; or other narcotics may be similarly employed. In the most severe cases vomitings or retchings may occur

and add to the patient's distress; for these the *oxalate of cerium* has been prescribed by my friend Dr. PANTON, conformably with the opinion entertained of the salts of cerium. In a case which I attended with Dr. PANTON, the oxalate of cerium was suggested by him, in doses of two grains, thrice daily, and gave great relief. Besides these, various means have been recommended to be applied either above the pubis or over the sacrum. Embrocations of turpentine containing opium, or warm epithems of turpentine, have often succeeded in giving relief in a short time when thus employed. Aconite or veratrum applied over the sacrum, has been resorted to; a small quantity of the extract or of the tincture of either of these being mixed in an ointment or liniment, but the use of these powerful sedatives requires caution, although externally applied. In some instances warm narcotic injections, repeated and varied according to circumstances, will be of service.

17. If this complaint be dependent upon chronic inflammatory irritation or action, or upon some other lesion of the uterus (§ 21, *et seq.*), the means required by such lesion should be adopted in addition to that which may appear most appropriate of the remedies now advised; and the *diet* and *regimen* of the patient ought to be regulated with due reference to such associations and to other peculiarities of the case. In the great majority the recumbent posture, varied as may be required, rest, and ease of body and mind, are necessary, and in all strict avoidance of the predisposing and exciting causes, both ascertained and inferred, should be insisted upon. A reference to these causes will show (§ 10, 22) that certain of them, when once indulged in, are not readily relinquished, and that persistence in them will render the most judicious treatment of no avail.\*

18. The means which are most suitable for the fulfilling of the *second* intention, viz., the restoration of the general health, and of the healthy state of the sexual organs more especially, are the same for this complaint as for accomplishing the second indication of treatment advised for the several forms of inflammatory irritation or action of the uterus (§ 108, *et seq.*). In some instances, in which I viewed neuralgic or very painful affections of the uterus as the result of the influence of malaria, I have during the intervals between the paroxysms, and with the view of restoring the healthy functions, prescribed either the arsenical solution in the usual doses, or the preparations of iron with quinine and camphor.

## II. INFLAMMATIONS OF THE UTERUS AND APPENDAGES.

[\* If the *uterine neuralgia* be secondary or sympathetic, our therapeutic measures should be directed to the removal of the primary cause, be it engorgement, ulceration, or displacement. If it be primary, we have generally found *cauterization*, with nitrate of silver, or the red-hot iron, successful in accomplishing a cure. In some cases it has been necessary, in addition, to insert an issue on the sides of the lumbar vertebrae or in the hypogastric region. If the pain be periodical, it should be met, as in case of other forms of neuralgia, by quinine, arsenic, &c. Temporary relief is afforded by suppositories of belladonna, hyoscyamine, and opium. In some cases relief will be afforded by the introduction of the uterine sound into the cavity of the uterus, as MALGAIGNER has advised, on the principle that it modifies the nervous sensibility of the mucous membrane. In some cases, where the pain has been very severe, we have found a combination of tinct. aconite and chloroform act very promptly in relieving it. They should also be used externally over the hypogastric and lumbar regions by friction.]

## CLASSIF.—III. CLASS, V. ORDER (Author in Preface).

19.—DEFINIT.—*Pain and weight or uneasiness in the hypogastric region, and behind the pubis, often with pain in the lumbar and sacral regions and in the regions of the ovaria, extending to the groins and tops of the thighs, with more or less symptomatic fever, increased towards evening.*

20. Inflammations of the uterus present very different phenomena and occasion very different results, according as the morbid action is seated chiefly or entirely in the neck of the organ, or in the body, or in the internal surface, of the uterus, or as it may implicate the peritoneal surface of the fundus. The symptoms vary also with the degree in which the adjoining viscera are affected either coetaneously or consecutively—with the nature and extent of the complications, so often presented by inflammation of this viscus; and they vary with the grade of morbid action, and with the manner in which the sensibility and sympathies of the uterus are excited.

21. i. INFLAMMATION OF THE NECK AND MOUTH OF THE UTERUS AND ITS CONSEQUENCES.—Inflammation of the cervix and os uteri is generally *chronic* and often very protracted. It is rarely acute unless it be caused by the gonorrhœal virus, several instances of this form of disease having come before me, one of them at the commencement of my practice, when the possibility of the occurrence was generally denied by the physicians of this country. But this specific form of the disease will be noticed hereafter. When inflammation attacks this part of the uterus it is often slight and insidious in its accession, and, being frequently attended by more or less discharge, is too commonly viewed as a form of leucorrhœa, and considered of comparatively slight importance. This circumstance often tends to its neglect at a period when a judicious treatment might have removed the disorder without any difficulty. But, being overlooked or neglected, and perpetuated or aggravated by persistence in the causes which occasioned it, the disease becomes most obstinate and protracted, and is followed by changes of structure which generally render the treatment more or less difficult. In all cases where the local and constitutional symptoms suggest even the idea of disorder or disease of the uterus, the advice given by a most eminent and able physician, M. CUOMEL, should be followed: "La fréquence et la diversité des affections de l'utérus, la forme latente de beaucoup d'entre elles, l'éloignement qu'éprouvent la plupart des femmes à parler des sensations et des dérangements dont cet organe est le siège, sont autant de motifs pour le médecin de porter de lui-même son attention de ce côté, d'adresser aux femmes les questions relatives à ce sujet, et enfin de ne négliger aucun des moyens d'exploration, toutes les fois que quelque circonstance en indique la nécessité. L'oubli de ce précepte deviendrait la cause d'erreurs de diagnostic aussi graves que fréquentes." Unfortunately the worst features of our common nature—the most bitter manifestations of the "*odium medicum*," which is generally the most bitter and unjust against those by whom success is achieved—have been displayed respecting a recourse to those means which are requisite to "exploration," and the existence of those lesions which are to be ascertained chiefly by the exploration in question—namely, by examinations *per vaginam*, by means

of the senses of touch and sight. On this subject it is quite unnecessary to remark farther, than that the abuse of any particular mode of investigation, or an improper recourse to and employment of it, cannot invalidate the proofs of the great advantages which are derived from its proper and judicious use; and that the evidence and practice of men of character, position, and experience, are not to be impugned or disparaged by others who are not entitled in any point of view to become the censors of their professional brethren.

22. *A. The causes of chronic inflammation of the neck of the uterus and its consequences* are those which have been enumerated as producing the two chief forms of altered sensibility of the organ (§ 10), more especially difficult or disordered or arrested menstruation, excessive sexual indulgences, and masturbation; falls on the back or hips, or injuries in the vicinity of the pelvis or peritonæum; difficult and instrumental labours and abortions; the extension of inflammatory irritation to the neck of the uterus from the vulva and vagina; gonorrhœal infection; the foul air ascending open privies; the use of pessaries; displacements of the womb; cachectic habits of body, and neglect of cleanliness. In many cases the cause of disorder is either not manifest or can only be inferred. The disease seldom occurs before puberty, or long after the cessation of the menses. It is most frequently observed from twenty to fifty years of age.

23. *B. Symptoms.*—The existence of inflammation of the neck and mouth of the uterus is evinced by the appearances of the part, by the local signs and symptoms, and by the sympathetic or constitutional phenomena. The appearances of the cervix and os uteri, it might be supposed, could not fail of evincing the existence of inflammation of them, more especially since those appearances have been disclosed by the use of the speculum. Even previously to the use of this instrument, this disease might have been detected by the sense of touch and the phenomena resulting from examinations by this sense, and by the secretions and alterations of sensibility attending it. If the appearances constituting inflammation of these parts admitted of doubt, and consequently of discussion—although discussion has not in this instance been always the consequence of either doubt or unbelief—surely the several results of inflammation, more especially tumefaction, excoriation, granulations, ulcerations, &c., need not have been misunderstood nor misrepresented. When treating of LEUCORRHEA in 1841 (published in 1842), I referred the two most important states of this complaint to “inflammatory irritation of the mucous glands of the os and cervix uteri,” and to chronic inflammation of the internal surface of the uterus, and contended that these forms of leucorrhœa, especially the latter, are not unfrequently of a specific inflammatory nature, or gonorrhœal. Of this specific form I have seen several cases, the first of which occurred at the very commencement of my practice (in 1821); the last very recently, the inflammation having extended to the Fallopian tubes. (See *art. LEUCORRHEA*, § 19, *et seq.*)

24. *a. The appearances of the cervix and os uteri* vary with the severity and character of the inflammation—with the amount of irritation and congestion preceding and attending it; with the intensity of the morbid action; with its duration

and the amount of exudation and secretions accompanying it; with its extension to the internal surface of the cervix; and with alterations of structure which may have already taken place. The earliest appearances are not always observed, for congestion or irritation, of a more or less inflammatory character, may have existed for a longer or shorter time before the complaint had advanced so far as to induce the patient to have medical advice. When the mucous surface of the cervix is simply congested or inflamed, it usually presents a red or livid hue, instead of the pink or pale rose colour of health; it is often dotted with florid papulæ, or with whitish pustulæ, according as its mucous glands are inflamed or distended with a muco-puriform matter. Frequently the surface of the cervix is covered with this matter so as to prevent its exact state to be observed until this secretion is removed. At first the cervix is somewhat swollen or enlarged, but still soft; but with the persistence of the inflammatory action, and with the exudation into the structure of the cervix, more or less induration is superadded. At this early period the os and cervix uteri are hotter and more tender or even painful to the touch than in the healthy state; but the amount of tenderness and of pain appears to depend more upon the temperament and susceptibility of the patient than upon the severity of the inflammatory action—or rather upon the irritable character of this action; the pain being in some cases, both in this stage and throughout the disease, such as to constitute the irritable uterus of several writers, as noticed above (§ 3, *et seq.*).

25. *b. As the disease becomes more chronic or protracted*, the cervix becomes somewhat elongated, and approaches nearer or almost lies upon the posterior part of the vagina. At the same time the os uteri is more open than natural, owing, in some cases, to the congestion, inflammation or enlargement of the muciparous glands at the orifice and internal canal of the neck, externally to the os internum of the uterus, and in others to congestion of its internal mucous surface and subjacent tissues. This inflammatory state of the mouth and canal of the cervix was shown, when treating of LEUCORRHEA (in 1841), to be a frequent cause and form of that complaint, as it is an associated condition of chronic inflammation of the cervix; and it usually presents a dark reddish or livid hue. The muco-puriform matter secreted by the inflamed mucous surfaces of the cervix varies much in appearance and quantity in different cases; but the chief part of this secretion, as I have stated in the article just referred to (§ 19, *et seq.*), manifestly proceeds from the cervical canal. The state and character of this secretion, especially upon its discharge, depend much upon the time of its retention in the vagina and upon the exclusion or access of air.

26. *c. Inflammation in the neck of the uterus* may continue a long time without giving rise to its usual results. This may be owing to the partial resolution it may experience from the exudation or secretion from its surface and from the mucous glands, or from the menstrual flux. But after an indefinite time, the mucous membrane of the cervix and os uteri, more especially that portion immediately surrounding the mouth of the cervical canal, undergoes farther change, generally commencing with excoriations or abrasions of the surface and passing on to ulcerations, but very rarely with loss of substance. These may

present minute red granulations, or vegetations of a livid hue. When an abrasion or excoriation is alone present, the surface is generally of a vivid red, and the granulations on its surface are very minute; this state of the lesion occurs chiefly within the mouth and canal of the cervix, and most frequently in single females. In a more decided form of ulceration, the granulations of the ulcerated surface may be firm, of a vivid red hue, scarcely bleeding on pressure, or they may be large, fungous, livid, and bleeding readily on a slight touch. Sometimes the granulations or vegetations on the inflammatory sore rise above the level of the surrounding parts, bleed profusely when they are touched, or even separate partially. Inflammatory ulceration of the cervix is rarely or never excavated; it is always on a level with or above the non-ulcerated tissues, and its margin never presents any abrupt induration. Hence the difficulty of determining its existence and limits by the touch, and the source of differences of opinion as to the existence of ulceration of this part. The cervix very seldom presents more than one ulceration situated around the mouth, dipping into its cavity, and extending more or less on the outer surface. If the ulcerated state consist of several patches, it may be referred to aphthous or ulcerated mucous follicles.

27. The form of the os uteri is generally changed, owing to the existence of the ulcerated state now described both within and around this part. The lips of the os swell, enlarge, expand, and open the cervical canal. This opening varies with the amount of inflammation and of the changes above described, but it is generally greatest in females who have had several children. When with these changes the lips of the os uteri are much hypertrophied and indurated, the opening may admit the first phalanx of one or even of two fingers, and it may then assume the form of two segments of a sphere, separated by a deep fissure, within which the ulcerated surface is situated.

28. Ulceration, or the changes now described as constituting the ulcerative state of the cervix and os uteri, gives to the surface of these parts a soft, velvety character, when examined by the touch. This sensation and the open state of the os uteri are the chief indications which this sense can furnish of the existence of this lesion; but, as inflammation alone will open the cervical canal, and as the velvety sensation cannot be depended upon, the existence of ulceration can only be determined by an instrumental examination. The state of the parts detected by touch, and the symptoms about to be noticed, warrant a resource to this examination. "In nearly all the cases in which ulceration occupies the exterior of the cervix, it will also be found, on examination, to penetrate more or less deeply into its cavity. The entire canal of the cervix, as far as the os internum, may be ulcerated. Even when the cervical canal is free from ulceration, if ulceration exists externally, it is generally inflamed to a greater or less depth." The natural coarctation of the os internum appears generally to constitute a barrier to the extension of ulceration into the cavity of the uterus. But to this rule there are exceptions, as respects the inflammatory state, which obviously extends in many instances.

29. *d. The discharges from the vagina* caused by chronic inflammation of the cervix uteri are identical with those which are described under

the head of *LEUCORRŒA*. For, as I described these in that article as resulting from inflammatory action, as evinced by the local and general symptoms (see § 19, *et seq.*), their connexion with the changes above described and disclosed by the speculum is obvious. The discharge generally consists of various proportions of mucus and pus, it is rarely the latter only or chiefly, unless the inflammation be specific or gonorrhœal. It is not unfrequently tinged with blood, especially after violent exertion or sexual intercourse. In these circumstances, the blood is exuded from the ulcerated or granular surface, and is seldom in considerable quantity—when in quantity it may be unmixed with the muco-puriform discharge.

30. *e. Hypertrophy* of the neck of the uterus is generally a consequence of chronic inflammatory action, congestion and swelling of this part being an early result. It may, however, remain long without farther change, its structure retaining its softness and elasticity. After a time, the exudation of plastic lymph in the interstices of its structure either is considerable, or becomes partially organized, and renders it both hypertrophied and indurated. At first the inflammatory action is often acute, as indicated by increased heat, vivid redness, and tenderness on pressure; but these signs subside, the hypertrophy advancing with more chronic indications; and sometimes so far as to very greatly increase the size of the cervix. In virgins and women who have not had children, the cervix seldom enlarges to any great extent. It may be indurated and yet not increased in size; but when it is enlarged in this class of patients it seldom is more than two or three times the natural size. In women who have borne children the hypertrophy of the cervix with induration may, according to Dr. J. HENRY BENNET, in extreme cases reach the size of the fist. Some French writers ascribe the ulcerations existing in these cases to the hypertrophy; but he justly contends that the ulceration may commence as early as the hypertrophy and advance with it; and he has seen ulceration confined to one lip, accompanied with induration and hypertrophy of that lip only. When the chronic inflammation causing these changes in the cervix has followed a miscarriage or delivery, the hypertrophy is generally the more remarkable. Hypertrophy and induration are commonly confined to the cervix, but sometimes they extend to the body of the uterus, indicating that it is also the seat of chronic inflammation.

31. As the indurated cervix enlarges, the external opening expands and assumes a transverse form; so that instead of a nearly circular orifice, there is a deep fissure with well-defined lips. This occurs more especially when the induration is attended by ulceration. Sometimes one of these lips may be many times larger than the other. When the superior lip is much enlarged it covers the os uteri, which is underneath it; when the inferior one is thus changed the os is above it. Dr. H. BENNET says that he has seen both the superior and the inferior lips separately enlarged to such an extent as to form a kind of tumour projecting a couple of inches beyond the non-hypertrophied lip. He states that the hypertrophied cervix is sometimes divided into separate lobes, owing to antecedent laceration of the cervix during an abortion or instrumental labour. The laceration not healing, the ulceration in the

course of time is followed by hypertrophy of the segments into which the cervix is divided. These segments sometimes assume a stony hardness; and they may be mistaken for scirrhus, but may be distinguished from that malady as follows: "When the lobular, knotty irregular condition of the cervix is the result of laceration, and is simply inflammatory, the fissures which separate the lobes radiate round the cavity of the os as a centre—which is not the case in a cancerous tumour—each separate lobe being perfectly smooth in itself, and free from tubercles, or superficial irregularities. Not only is this lobular form of induration erroneously considered cancerous, but even the hard inflammatory hypertrophy is still more erroneously considered to be frequently malignant."

32. *f. Displacement* is often consequent upon inflammatory hypertrophy of the cervix; the entire organ generally descends, and the cervix is thus brought nearer the vulva, and at the same time directed backward. The retroversion of the neck of the uterus is commonly met with in married females suffering from inflammatory induration. With them it is chiefly owing to intercourse, and generally becomes permanent. Enlargement and induration, when very considerable, often occasion more or less prolapsus, unless the vagina be very contractile. In women who have had many children, and in whom the vagina is lax, and offers an insufficient support to the uterus, the prolapse may be so great, especially when standing, as to reach the vulva, or even to appear externally. When the cervix thus lies low in the vagina, a sensation of weight, dragging, and bearing down is experienced, especially when erect. This sensation is caused by the traction of the organ on its ligaments and organs with which it is connected, and by the pressure of the cervix on the vagina and vulva. The hypertrophied cervix may be directed anteriorly, or behind the pubis, and be more or less high. This position is generally owing to some enlargement of the body of the uterus, causing the organ to fall back into the cavity of the sacrum, thus throwing up the cervix. The enlarged cervix occasionally lies diagonally, or to either side, but this position seldom amounts to a diseased condition.

33. *g. Pain* is not always experienced in chronic inflammation of the neck of the uterus, and when it is felt, the situation of it is very often such as not to designate the seat of disease. In some cases pain is almost or entirely absent, although there may be leucorrhœal discharge, and considerable constitutional disturbance, even with slight feverish symptoms towards evening. My experience enables me to vouch for the accuracy of Dr. J. H. BENNETT's remarks respecting the seat of pain; for in several cases to which I have been called, an examination has confirmed the connexion of the pain with the local affection. The pain is dull, aching, constant, and generally circumscribed, usually felt in one or both the ovarian regions, but much more frequently in the left than in the right; pain of a similar character is also often experienced in the back, and even still more frequently, according to my experience, in the lower region of the sacrum, just above the os coccygis. When it is felt in this situation the neck of the uterus will be found low in, and pressing upon the posterior walls of, the vagina. Sometimes the pain in the

back is scarcely perceptible, or is described only as a "weakness," excepting after fatigue, when it is usually more severe. The patient says that her back is broken, and that she can neither stand, sit, nor walk with comfort. "When there is pain in the region of the uterine neck, it is experienced behind and above the pubis. It is seldom circumscribed, like the ovarian pain, but radiates all over the lower hypogastric region. These three pains—the lumbo-sacral, the ovarian, and the lower hypogastric (I name them in the order of their relative frequency)—may exist conjointly or separately. They are produced alike by inflammation without ulceration, and by inflammation with ulceration. They are, however, much more marked when there is ulceration, more frequently severe, and much more constant."

34. These pains are not to be mistaken for *neuralgia* of the uterus, which is much more acute, comes on suddenly after intervals, and ceases as suddenly, and is seated in the uterus itself (§ 14, *et seq.*). The neuralgic pain is sometimes present only for an hour or two, and rarely longer than ten or twelve hours, the intervals being characterized by freedom from pain. It is sometimes symptomatic of organic disease of the womb, as fibrous tumours in the structure of the organ. But it is often felt independently of any evident lesion, the os and cervix uteri being healthy and free from any morbid sensibility.

35. In addition to the pains described, the patient sometimes complains of pain in the hip, round the crista of the ilium, in the groin, and down the thigh; posteriorly along the course of the sciatic nerve and its divisions, and anteriorly and internally along the course of the anterior crural and obturator nerves. These pains I have referred rather to chronic inflammation of the inner surface of the uterus and enlargement of the organ than to chronic inflammation of the cervix. In the former case they may be caused by deficient support of the vagina, partial prolapse and pressure; in the latter case they may be sympathetic. The pains caused by diseases of the uterus are always increased by standing, sitting, walking, and exertion, but relieved by reclining and the horizontal posture.

36. *h. The functions of the uterus* are often interfered with during the continuance of chronic inflammation of the cervix. As respects *menstruation*, it may be stated, that it may for a time go on without any marked change. But it usually becomes more painful, very scanty, or excessively abundant, and irregular as to the interval, the duration, and the quantity. The pains, especially on its accession of this period, are greatly increased in the situations above described, and are often attended by retchings and vomiting, by recurring uterine tormina, and by marked tenderness of the hypogastric region. The irritation, congestion, enlargement, and other lesions of the cervix become aggravated during this period.

37. This disease must necessarily be a cause of sterility in many instances, the morbid states of the cervix and os, and the discharges from them, interfering more or less with impregnation, not only in recently-married females, but also in women who have borne children. Some females, however, become pregnant, notwithstanding the existence of extensive disease of these parts; but when it takes place under these circumstances it is generally painful, and apt to termi-

nate in abortion. Sterility proceeding from this disease may be removed by curing its cause. Dr. BENNET states that he is continually seeing patients who have ceased child-bearing for years, owing to inflammatory disease of the cervix, recover the power of conception when the local affection is cured. Sometimes they become pregnant even before they are quite well, in which case they seldom miscarry, even if the treatment is suspended, although the pregnancy is often laborious.

38. *i. Uterine inactivity*, or exhaustion, is often a symptom of chronic inflammation of the os and cervix uteri, especially when attended by profuse leucorrhœa and ulceration or granulations, or when the disease is severe. Dr. J. H. BENNET remarks that this absence of natural sensations, or sexual desire, sometimes exists independently of any physical pain, and occasions great unhappiness in married life. He attributes this change to the modified vitality of the diseased uterine organs and impaired general health. The cases of this description which I have met with have been chiefly those in which there was reason to believe that the complaint had been caused by self-pollutions, and where the tenderness of the os uteri and adjoining parts rendered sexual congress more or less painful; for instances are not rare of masturbation being persisted in, although marital congress is resisted or evaded. When the cervix is so tender from this disease as to render congress painful, the sensation is experienced at the time and for some hours afterward, or even longer. It may be felt either behind the pubis or in its usual situations. But although the disease may be severe, the cervix being ulcerated and enlarged, congress may not be painful. Whether painful or not painful—the former especially—this act may be followed by a discharge of a little blood, or even by considerable hæmorrhage. That the evasion of marital congress is owing rather to the circumstance just adverted to than to the disease of the cervix, is evinced by the fact that such evasion is not manifested in other diseases of the uterus, or very rarely.

39. *k. Constitutional and general symptoms* are always present when the cervix uteri is diseased. It should not be overlooked that this part of the uterus possesses marked sensibility and intimate relations with all parts of the economy, through the medium chiefly of the ganglial and sympathetic system. Hence the digestive functions are more or less disordered according to the duration and severity of the local complaint; and there are frequently both nausea and vomiting on the accession of the catamenia. The disorder of the stomach and digestive organs is often somewhat similar to that consequent on early pregnancy, and is the consequence of the inflammation. The leucorrhœa so generally present has been too often imputed to this disorder of the digestive organs, instead of these complaints being regarded as results of the inflammation of the cervix. The urinary function is often more or less disturbed, in respect both of the saline constituents of the urine, and of the frequency of the calls to discharge this secretion, and the sensations attending the act. Dysuria is sometimes complained of, and a portion of the secretion from the inflamed cervix often passes from the vagina at the time of micturition.

40. The *pulse* is sometimes very materially affected, and becomes more or less accelerated to-

wards evening; and, as debility increases, it is generally weak, or small and irregular, and readily accelerated on any mental or physical excitement. A protracted state of the disease, especially when characterized by granulation, ulceration, and abundant leucorrhœal discharge, ultimately occasions anæmia, pallor, a sickly or sallow appearance of the countenance, loss of flesh, and a flabby state of the muscular structure. Contingent upon the course of the disease, various sympathetic affections often appear, especially nervous headache, depression of mind, a sense of weight or pressure at the summit of the head or on the forehead, pain and tenderness in the course of the spine, and numerous hysterical symptoms. These phenomena are generally exacerbated during the catamenial period, especially when this period is disordered in any way. Most of the symptoms described in the articles HYSTERIA and SPINAL IRRITATION originate in this disease of the cervix and os uteri.

41. Dr. J. HENRY BENNET was the first who gave full accounts of the diseases of the cervix of the uterus; and he was followed by Dr. WHITEHEAD of Manchester, Professor SIMPSON of Edinburgh, and Professor MILLER of Louisville, U. S. Various other writers on uterine diseases have coquetted with the subject, and, after having endeavoured to controvert the statements of these physicians, have at last fallen in with their views. From these and other sources of information, furnished not only in this country, but even much more abundantly on the continent, as will be seen in the BIBLIOGRAPHY, the great importance of inflammatory disease of the cervix uteri is made apparent. Dr. WHITEHEAD has given an enumeration of the lesions of this part of the uterus; and, although I do not profess this or any other specialty, but endeavour to practise as a physician in all medical cases, yet I am sometimes consulted respecting uterine diseases, and I am thus enabled, from some experience, to say that the statements and descriptions furnished by the physicians whom I have mentioned are unassailable.

42. "1st. Inflammation and superficial erosion, implicating one or both lips of the os uteri, and more or less of the external and internal cervix; 2d. Varicose ulceration, commonly occupying the back part of the anterior lip, sometimes confined to the posterior, and occasionally implicating both. It gives rise to hæmorrhages obeying, more or less perfectly, the menstrual periods, and to purulent discharges in the intervals; 3d. Edema of the cervix; 4th. Fissured ulceration of one or both commissures, of the anterior or posterior lip, or implicating all these parts at the same time; 5th. Induration of the cervix, with or without abrasion of surface; 6th. Endo-uteritis, or inflammation of the lining membrane of the uterus, affecting the body as well as the neck, and sometimes accompanied with induration of the cervix, or erosion of one or both lips of the os uteri; 7th. Follicular ulceration; 8th. Gonorrhœal inflammation, affecting the lips and adjacent cervix, and especially liable to spread to the lining membrane of the entire organ; 9th. Syphilitic disease in its primary, secondary, and tertiary stages; 10th. Prolapsus uteri, which owes most commonly its existence to disease of the lower part of the uterus, as the primary exciting condition."

43. To this enumeration of lesions, given by

Dr. WHITEHEAD, may be added *hypertrophy*, with or without ulceration, or granulation, or dilatation of the cervical canal. This, in one or other of these states, is a frequent consequence of chronic inflammation of the cervix. *Gonorrhæal inflammation* of the cervix and its canal is of greater importance than is usually considered. I have seen several instances of this form of disease, and in nearly all it extended to the lining membrane of the uterus, and was accompanied with great suffering. In three cases of married ladies, not only did this extension occur, but the *ovaria* also became remarkably enlarged. Recovery ultimately took place, but the *ovaria* remained more or less enlarged in all.

44. *C. In the virgin and unmarried female*, inflammation and its consequences noticed above are by no means infrequent; and, although partially described by me in the article *LEUCORRHEA* in the section on "*Leucorrhæa from inflammatory irritation of the mucous glands of the os and cervix uteri*" (§ 19, *et seq*) before the appearance of Dr. HENRY BENNET's work, yet to him the distinction is justly due of having first fully described and elucidated this subject in respect of this class of patients; and I can fully corroborate his statement that inflammation and ulceration of the cervix uteri in the virgin is not an uncommon disease, and that to it may be referred most of the severe forms of dysmenorrhœa and leucorrhœa which resist the ordinary modes of treatment. Even within these few months I have been called to several cases, under the care of other practitioners, where this disease existed, from ages varying from nineteen to thirty. Scanty, excessive, and irregular menstruation, as well as the complaints just mentioned, not unfrequently proceed from inflammatory states of the cervix, and internal surface of the uterus, as shown in the article on *MENSTRUATION*. (See more especially § 85-129.)

45. The causes of inflammation of the cervix uteri in unmarried females have been already noticed. (§ 10, 22.) The symptoms in them are not materially different from those already described: the permanency of a leucorrhœal discharge; the local pains; dysmenorrhœa, and otherwise disordered menstruation; spinal irritation; sympathetic pains in the hips, thighs, spine, and under the left mamma; bearing down, weight in the pelvis, debility, pallor, anæmia, emaciation, &c. In addition to these, *partial prolapse* of the uterus, and other deviations of its position, are not infrequent in this class of patients.

46. *D. During pregnancy* inflammation and ulceration of the os and cervix uteri may be present, having existed previously, or supervened subsequently to impregnation. MM. BOYS DE LOURY and COSTILHES first noticed this state of the disease; and soon afterward Dr. HENRY BENNET, in 1846, and Dr. WHITEHEAD, in 1847, fully illustrated this association of inflammation of the cervix uteri. Dr. BENNET remarks that he formerly believed that the disease mostly originated subsequently to conception. This opinion, however, his later experience on a wider field has shown to be erroneous. Although it sometimes thus originates, the cervix is diseased in the majority of cases previous to conception. He adds that the disease generally produces sterility when it attacks young married females at the onset of their married life, but not so generally arrests

conception when they have had children before they are attacked. The indications furnished by tactile and ocular examinations in this state of the disease are the same as already described. The disease is attended by pains in the back, sacrum, above and behind the pubes, and by a sense of weight and bearing down, and mucopurulent discharge. As pregnancy advances the pains increase; the sickness and vomitings attending this state become severe; and the mucopuriform discharge is often accompanied with more or less hæmorrhage. Dr. H. BENNET has very satisfactorily shown that this disease in the pregnant state is often a cause of the various disorders complained of in this state, or hæmorrhage, obstinate sickness, death of the fœtus, abortion, moles, &c.; and Dr. WHITEHEAD has fully corroborated this statement. These are most important practical facts; and, however sneered at by some, doubted by others, and disbelieved by a few, I have had occasions, since the date above mentioned, to be convinced of the truth of the statements made by these physicians. I may here adduce a summary of Dr. WHITEHEAD's researches on the influence of the lesions under consideration in producing abortions; and in this he confirms what had been previously adduced by Dr. H. BENNET. Inflammatory ulceration was the cause of abortion in 26 in every 100 cases; and this event occurred between the middle of the sixth and the middle of the ninth month of pregnancy. Varicose ulceration induced abortion in 6 or 8 out of every 100, and it operated during the latter two or three months. Œdema of the cervix, acting likewise in advanced pregnancy, was observed in about 1 in 25 or 30 cases. Fissured ulceration was found to exist in 20 to 24 out of every 100 cases, and may cause abortion from the fourth to the middle of the seventh month.

47. *E. During and after abortion and parturition*, inflammation, ulceration, and induration of the neck of the uterus are often productive of much and serious disorder. Induration, enlargement, and rigidity of the os and cervix uteri, in abortion or in labour at the natural period, render these acts both difficult, painful, and prolonged; and these lesions of this portion of the uterus, as well as ulceration, often occasion hæmorrhage after abortions and parturition, and this hæmorrhage is frequently followed by profuse, purulent, or muco-purulent discharge. "When the patient first attempts to rise and walk, she feels a sensation of weight and bearing down, which gradually increases, instead of diminishing. If the hæmorrhage and purulent discharge are continued and abundant, and the uterine pains are very severe, several weeks often elapse before she is able to leave her bed; and when she does, she remains weak, languid, and is unable to make the slightest exertion." Inflammatory ulceration, during the first stage of the puerperal period, powerfully predisposes to puerperal fevers, and to abscess of the ligaments. It is so commonly developed after abortion, Dr. BENNET remarks, that he always looks for it when the patient does not rally, but presents the symptoms already described.

48. *F. In advanced life, and after the cessation of the menses*, inflammation and ulceration of the neck of the uterus are sometimes met with. At this period, especially when the menstrual epoch has long ceased, ulceration is the form which in-

flammation of this portion of the uterus generally assumes. The most prominent symptoms at this epoch are severe and constant pain in the sacrum and lower part of the back, less severe and less constant pains in the ovarian regions, and in the hypogastrium, leucorrhœal discharge in some cases only, and bearing down and prolapse of the uterus much less frequent and more slight than in younger females. Ulceration of the neck of the uterus, in advanced age, seems to be oftener the remains of inflammatory disease present at the time when the menses ceased, than an affection which had commenced subsequently to that period.

49. ii. INFLAMMATION OF THE BODY OF THE UTERUS IN THE NON-PUERPERAL STATE.—SYNON.—*Metritis*; *Hysteritis*; *Inflammatio Uteri*.—Inflammation of the womb may assume various forms or states. It may be *acute*, *sub-acute*, or *chronic*; it may be *sthenic*, or *asthenic*, or *septic*; it may be *common* or *specific*; and it may affect either the *internal surface*, or the *whole body* of the organ. In the article on PUERPERAL DISEASES I discussed *Inflammations of the Uterus, its Appendages, and Vcins* (see § 176, *et seq.*) with reference to the several puerperal conditions; and I now proceed to consider those forms of inflammation of this organ which I have now mentioned, and as they commonly occur in the non-puerperal state.

50. A. INTERNAL METRITIS.—*Endo-Metritis*.—*Non-puerperal Inflammation of the internal surface of the womb*, in its most frequent forms, has been partially considered under the head LEUCORRHEA (§ 25, *et seq.*) and MENSTRUATION (§ 78-129). I have there shown that inflammatory states of the internal surface of the uterus may occasion certain forms either of leucorrhœa, or of menstruation, varying with the modified states of vascular action, not only in the uterus, but also in the cervical canal; the morbid action being rarely limited to the former, but generally extending to the latter, and often also to the substance of the uterus. Dr. H. BENNET considers that a *sero-sanguinolent* discharge is as characteristic of endo-metritis as the rust-coloured expectoration is of pneumonia. The internal cavity of the uterus in health is not much larger than that of the neck; but it is not improbable that, during the period of menstruation, or when congestion or inflammatory action exists in this part, this cavity may be somewhat enlarged, as, indeed, the whole organ frequently is in these circumstances. If in addition to the discharge just noticed, there be a dull, deep-seated pain behind and slightly above the pubis, and more or less general febrile reaction, endo-metritis may be confidently inferred. Since, in the introduction of the uterine sound, and its improvement by Professor SIMPSON, a recourse to it has been considered as a means of diagnosis in endo-metritis; for, if the os internum of the cervix be so completely open as to allow the uterine sound to pass freely into the uterine cavity, and if this cavity be increased in size, and be more sensitive, the above symptoms being also present, this complaint is certainly present. But endo-metritis may exist and not be attended by the sero-sanguinolent discharge alluded to. It is only when the inflammation is most severe that it is present. In the less severe and congestive states, it is characterized by the discharges and the symptoms described in the sections on LEUCORRHEA above

referred to, and, during the menstrual periods, by the painful, difficult, inflammatory, or hamorrhagic symptoms described in the article MENSTRUATION. (See § 78-129.)

51. As endo-metritis is commonly attended by chronic inflammation of the cervix and os uteri, the symptoms of the latter are generally present. Nevertheless, the former gives rise to nearly the same symptoms; yet the deep-seated and constant pain behind and partly above the pubis, the sensation of weight and bearing down, the swollen, sensitive, and enlarged conditions of the organ evinced on examination, the states of the discharge and of menstruation already noticed, and the accompanying febrile action, although often slight, but always increased towards night, sufficiently indicate the nature of the disease.

52. The progress and termination of endo-metritis depend much upon its causes and the circumstances in which it originated. It is often attended by more or less inflammatory action in the cervical canal, and in the substance of the organ; and, according to the extent of this association, to the occurrence of the disease after difficult or instrumental labours or after abortions, and to the domestic, moral, and hygienic conditions of the patient, the course, duration, and termination of the complaint should be imputed. A *chronic form* of the disease is apt to supervene, especially in the circumstances now alluded to; and even in favourable cases the acute form generally passes into the chronic, the constant discharges from the internal surface and neck of the uterus, whether sanguinolent, serous, mucopuriform, or purulent, and the catamenial discharges, whether difficult, scanty, or excessive, or attended by coagula, or by plastic exudations, ultimately tend to reduce the acute into a chronic state of the disease. *Ulceration* of the internal surface of the uterus has been rarely noticed as a consequence of endo-metritis. When this occurs, the cavity of the uterus is considerably enlarged, and contains pus, mucus, and a bloody matter, which are discharged more or less freely, and often at intervals. Dr. HALL DAVIS examined the uterus of a woman which exhibited these appearances, with several large ulcerations in the internal surface.

53. B. ACUTE METRITIS, in the non-puerperal state, is a rare disease. At the commencement of my practice (in 1822), having described an undoubted instance of it, at a meeting of a medical society in this city, the case was considered apocryphal. Since then, I have been requested to see other cases, both simple, specific, and complicated, but in most of them the inflammation had commenced in the neck and internal surface of the uterus, or had extended to these parts, and thence to the body of the organ, and in some instances to the uterine appendages. On referring to the notes which I took of the more remarkable cases—since the one in 1822—which I have seen, I find that the disease occurred in seven married females who had never been pregnant, and in three unmarried females. In four cases it was referred to gonorrhœa communicated by their husbands, and in three of those the disease extended to the uterine appendages, the ovaria becoming acutely inflamed and ultimately remarkably enlarged. These four females had never been pregnant. I have notes of the disease as I observed it in six married females who had had

children, but who had not been pregnant for a very considerable time previously to their attacks. In two of these last, the cause and course of the disease were so singular as to require a more particular notice in the sequel. Within these few years other cases have been seen by me; and I am at this time seeing in consultation a very acute case of the disease in a single woman. In none of these instances could any doubt be entertained as to the seat of the malady.

54. *a.* The seat of metritis is the whole body of the uterus; but the disease may commence in different ways. It may attack the whole organ primarily, or extend to it from the internal surface of the neck. These parts may themselves be affected consecutively upon inflammation of the vulva and vagina, especially when they are inflamed by specific, or asthenic, or contaminating causes. Inflammation of the body of the uterus, in the non-puerperal state, seldom extends to the peritoneal surface so as to give occasion to either partial or general peritonitis, as so generally observed in puerperal metritis. An instance, however, occurred, to which I was called towards its close, of a lady who had been treated by very astringent injections for the removal of profuse discharge from the internal uterine and cervical surfaces. With the suppression of the discharge, acute metritis supervened, and was very rapidly followed by inflammation of the peritoneum covering the pelvic viscera, and ultimately by death; the progress of the disease being manifested by examination after death. Metritis, in very rare cases, may occur in the non-puerperal state from the extension of inflammation from the rectum or bladder. Many years ago I attended, with Dr ROBERT LEE, a married lady, who was attacked at first with dysenteric tenesmus, manifestly owing to inflammatory action which had commenced in the rectum and sigmoid flexure of the colon. Soon afterward unmistakable evidence of acute metritis appeared. This lady had not conceived for several years. Soon after the full development of the metritis, which was attended by intense suffering, phlegmasia alba dolens of the left thigh began to appear, and when the subsidence of it commenced, the right thigh became similarly affected. She ultimately recovered. But disease may commence almost simultaneously in the rectum and vulva from certain septic emanations, especially in females who have had children. I was called to two families living in the opposite outskirts of London, during a very warm autumn, after a hot summer. The privies of both houses were open, very full, and offensive. Several younger members of these families were attacked by dysentery, with distressing tenesmus, and their mothers became the subjects of both the dysenteric affection and asthenic inflammation of the vulva, rapidly extending to the vagina, and to the neck and body of the uterus. In both these cases the symptoms of acute metritis were unmistakable and most violent, and were, with the dysenteric affection, manifestly caused by the state of the privies, to which, indeed, the patients themselves referred them. I have, both in this and in foreign countries, had frequent reason to impute the occurrence of DYSENTERY (see § 24) to open privies, &c.; but these two are the only instances I recollect of both dysentery and acute metritis having appeared coetaneously in the same female.

55. *b.* *Symptoms.*—The patient complains of

severe and constant pain deeply seated in the hypogastric region, chiefly behind and above the pubis, darting into the ovarian regions, around the hips, and sometimes down the thighs, with a sensation of weight and uneasiness in the pelvis, and of severe pain of the lower lumbar, lumbodorsal, and sacral regions. Pain, on firm pressure, is felt just above the pubis, in the median line, and equally to the right and left of that line. On examination, the vagina is generally hot and dry; the cervix and os uteri are swollen and sensitive to the touch or to pressure. The body of the uterus is enlarged, and attempts to ascertain its size are attended by extreme pain, and often by nausea or retchings. The symptoms are always aggravated by sitting down on a hard seat, or by an examination per vaginam, and the patient is unable to walk or stand, or to sit up in bed. She generally lies on her back with her knees drawn partially upward. Calls to pass urine are frequent, and attended by dysuria. The bowels are usually constipated, and costive motions are passed with extreme pain and difficulty, the hardened faeces being surrounded by much mucus. In many cases violent paroxysms of pain occur after intervals of comparative ease.

56. This acute state of the disease is not often preceded by chills or rigors, and it is at first not attended by any vaginal discharge, unless it have supervened upon vaginitis, or endo-metritis, as in some cases of asthenic or diffusive inflammation of the vagina and vulva. However, when the inflammation has commenced in, or extended to, the inner surface of the uterus (§ 50), a sero-sanguinolent, or purulent discharge takes place. As the disease subsides, a copious discharge, of various appearances, occurs. In addition to the usual febrile or constitutional symptoms, especially thirst, restlessness, scanty, high-coloured urine, constipation, headache, want of sleep, &c., there are constant nausea; a white or furred tongue; pain and swelling of the mammae, and sometimes hysterical symptoms, but chiefly in nervous and hysterical females. In less severe cases the symptoms are milder, and the nature of the complaint is evinced chiefly by a careful digital examination.

57. *c. Terminations.*—In from seven to fourteen days the disease subsides, generally without either suppuration or inflammation of the uterine veins, in the non-puerperal state; but this latter result may occur in this state, as shown in the case attended by Dr. R. LEE and myself (§ 54), and in two other cases for which I was consulted, and which terminated fatally, the uterine phlebitis having been followed by secondary purulent formations, as shown by examination after death. It is chiefly in the cachectic habit of body in females addicted to intoxicating liquors, as in one of the two cases just now alluded to; and when the causes are of a septic or infecting nature, and the disease assumes an asthenic character, that either the veins become implicated on the one hand, or the peritoneum on the other.

58. Acute metritis may degenerate into the chronic state, and occasion the inflammatory forms of *leucorrhœa* and of disordered *menstruation* (see those articles), or various consecutive lesions; and it may give rise to purulent collections, either near to, or even in the cavity of the uterus. In either case the collection, as it becomes increased, is evacuated sometimes more or less suddenly, and after a greater or less increase

of suffering, per vaginam. When matter is formed near the outer surface, it most frequently extends to the cellular tissue between the lateral ligaments, and finds its way, as in cases of suppuration occurring in those ligaments.

59. *d. The prognosis* of acute non-puerperal metritis is generally favourable when the constitution of the patient is sound; when the disease is treated promptly and judiciously, and the causes are not of a contaminating or specific nature, as in the cases above alluded to (§ 54). In drunken females, in the cachectic, and when the disease has been produced by infectious or contaminating agents, the extension of inflammation to the ovaria, to the veins, or to the peritoneum, should be dreaded; and in either case the patient's life may be placed in the utmost jeopardy. Even if the acute should lapse into the chronic state, or give rise to chronic inflammation of the lateral ligaments, much and prolonged suffering will result.

60. *e. Diagnosis.*—Acute metritis may be mistaken for acute cystitis, or the latter for the former. But a careful examination of the hypogastric region, of the state of parts per vaginam, and of the condition of the urine and the phenomena attending the discharge of it, will readily disclose the organ affected. When the lateral ligaments are inflamed, the pain and tenderness on pressure are experienced on one side of the median line, or in one side of the pelvis; "and the finger passed up towards the uterus, detects the inflammatory tumour lying on one side of the uterus."

61. *f. Examinations after death* from acute metritis in the non-puerperal state are rare, unless death has been caused by uterine phlebitis or by peritonitis, as in the cases alluded to above which occurred in my practice. In these cases the uterus was considerably enlarged, and very much softened, especially towards its internal surface. The substance of the organ was infiltrated with a dark ichorous fluid in one case, and with a greenish brown fluid in the other. The cavity of the uterus was much enlarged in both, but much more so in one than in the other, and its surface was covered with a chocolate-coloured or rusty exudation in the one, and by a rusty purulent exudation in the other; this latter containing a little of a softer matter of the same appearance and of an offensive odour. The spermatic veins were inflamed, and contained coagulated blood, phlebitis extending throughout the uterine and spermatic veins to the vena cava, with coagula mixed with an ichorous or sanious purulent matter. In one case purulent collections, more or less of a sanious appearance, and offensive odour, existed in the liver; and in another, matter was formed in one of the eyes, which had burst shortly before death. In a third case above alluded to (§ 57) peritonitis supervened, the uterus presenting but slight alterations of structure, but the *peritoneum* exhibited the lesions described in the article on this membrane. (See § 80, *et seq.*)

62. *C. SUB-ACUTE AND CHRONIC METRITIS.*—*Sub-acute metritis* is merely a less severe form of the acute, most of the symptoms described above (§ 53, *et seq.*) being present, but in a slighter degree. The *chronic* form of the disease may, like the acute, vary much in severity; but, unlike it as respects frequency, is a common form in its simple and complicated states. It gener-

ally is seated in a part of the body of the uterus; and, in the opinion of Dr. H. BENNET, in nine cases out of ten in the posterior wall of the organ, in its inferior region, adjoining to the base of the cervix. It is commonly the result of extension of ehronic inflammation of the cervix, and in some instances of the acute or sub-acute state of the disease. In these instances it may exist either in the anterior wall, or in one of the lateral walls, of the uterus.

63. *a. The symptoms* vary much with the exact seat of the disease, and with the periods during or near menses. In the intervals between these periods the patients are comparatively easy; the local symptoms are either much mitigated, or but little complained of; and fever is either slight, or experienced chiefly in the evening or night. In many cases, however, the functions of digestion, assimilation, and nutrition are impaired, and various nervous symptoms are experienced. When the vascular determination preceding menstruation supervenes, then all the symptoms characterizing the disease are developed. A constant, dull, aching pain is felt in the lower hypogastric region, behind and a little above the pubis, and in the left or right ovarian regions, most frequently the left. A dull aching pain is also present under the left mamma or in the left hypochondrium, in the lumbar-sacral region, extending around the hips, and down the insides of the thighs, and is often more complained of than the deep-seated pain in the pelvis. Walking, descending a stair, or riding in a carriage, and every kind of motion, are extremely painful, more especially before, during, and after menstruation; and in some cases are then agonizing. On the accession of this period, the patient's sufferings are sometimes aggravated by sickness and vomiting.

64. On examination per vaginam, in addition to co-existing disease of the cervix, the seat of disease is easily detected. The finger, when passed to the base of the cervix, and around it, meets with an exceedingly sensitive elevation, in some cases regular, in others irregular, but spherical. Pressure on the tumefied part is very painful. Occasionally there is hardly any perceptible swelling, but exquisite tenderness, pressure giving rise to sickness. The womb is generally movable, but the attempt to move it is attended by pain and nausea. Owing to its mobility, inflammation and enlargement of a portion of the uterus is generally attended by more or less displacement of the organ, which falls more or less in the direction of its enlargement. If the posterior wall be the seat of enlargement, as is most commonly the case, the organ falls backward towards the cavity of the sacrum, and the cervix is turned upward and towards the pubis, producing *retroversion*; but never in such a manner as to press upon the urethra, as sometimes occurs in retroversion during pregnancy. The cervix, however, may remain in its usual position, and not be anteverted, it forming an angle with the body of the uterus, which is said to be *retroflexed*. If it be the anterior wall which is tumefied, the uterus may fall forward, especially in married females, and occasion *anteversion*. When retroversion is connected with much enlargement, the uterus presses upon the rectum, and becomes a mechanical obstruction to the process of defæcation. In both forms also of displacement, especially when very marked, considerable disorder

of the functions of the urinary bladder results, the calls to urinate being often, difficult, or otherwise affected. Chronic metritis affecting chiefly one of the sides of the uterus, or associated with disease of the appendages of that side, may likewise occasion more or less displacement in that direction; but this is comparatively rare. Chronic metritis may not be necessarily attended by any vaginal discharge; but such discharge is most frequent, owing to the co-existence of inflammation of the cervix and vagina, and is either mucopurulent, or purulent with a more or less sanguineous tinge.

65. *b. The constitutional symptoms* of this disease, especially when protracted, are well marked, and are, according to my observation, well described by Professor SIMPSON and Dr. H. BENNET. The countenance is generally pale and sallow, and offers an expression of languor and pain; the "*facies uterina*" being more especially manifested by this malady, and particularly during or near the period of menstruation. Emaciation is a frequent sign, although not always recognised or recognisable at first. Nausea is generally present; in the most severe cases it is almost constant; in the less severe, only at the accession or during menstruation. Nausea, or sickness with loathing of food, but without vomiting, is so characteristic a symptom of metritis that, when it is present in chronic inflammation of the cervix, the extension of the disease to the body of the uterus may be inferred. Besides the intimate sympathy existing between the stomach and uterus, numerous other sympathetic derangements occur in the course of the disease, more especially palpitations, heartburn, headache, feverishness, want of sleep, restlessness, morbid states of the urine, constipation, dysuria, painful defæcation, &c.

66. *c. The progress and terminations* of chronic metritis are very variable. It is generally present for some time before the symptoms mentioned above are developed. It is at first attended by slight or obscure symptoms, which become more severe about the period of menstruation, and more and more constant with the advance of time, until the patient is prostrated by their severity and continuance. While recurring menstruation, by the vascular determination and congestion characterizing it, tends to exacerbate the disease, the vascular discharge, especially when considerable, reduces the severity of it, favouring a partial resolution, and perpetuating the chronic condition, when unaided by judicious treatment. When, with the periodical exacerbations, other causes of developing uterine inflammation are conjoined, the chronic may pass on to the acute form, and, in either form, may be extended to the uterine appendages, or even to the peritoneal surface. Cancerous degeneration of this state can rarely or never occur, unless in the cancerous diathesis. The most common consequences of chronic metritis are those already noticed, namely, displacements, enlargements, and the extension of the disease to adjoining organs or parts.

67. *d. Diagnosis.*—Patients affected with chronic metritis, existing either simply or with chronic inflammation and ulceration of the cervix, but a few years ago, were generally considered as subject only to functional dysmenorrhœa, or to displacements of the uterus. Dr. HENRY BENNET referred these latter to chronic metritis,

and viewed them when present as consequences of metritis, which, however, might exist without having as yet been followed by these consequences. Whether or no displacements of the womb ever occur without previous inflammation and its consequences, enlargement, &c., becomes a question, and one which requires solution; but there appears no reason to doubt the fact of the latter often producing and frequently being associated with the former. However, it should not be overlooked that, when an enlargement of the uterus is great, when it is not attended by any considerable pain or tenderness on pressure, it very probably arises from the formation of a fibrous tumour in the uterine walls. In these cases, there is generally displacement in the direction of the uterine tumour. When the tumour is large, it is often attended by more or less inflammatory action; and when this obtains, then both pain and tenderness may be expected. "An inflammatory tumour also of the broad ligaments may be mistaken for chronic metritis, occupying the lateral region of the womb, especially if the tumour be lying on the uterus, as is often the case." The symptoms characterizing the latter affection will be noticed in the sequel; but both affections are sometimes associated.

68. It may be difficult to distinguish *cancer* of the womb from chronic metritis. If the uterine swelling presents nodosities or irregularities of surface; if the pains are lancinating; if the general health is very much impaired; if the patient is sallow, cachectic, emaciated, anæmied, and weak, well-founded suspicions of cancer may be entertained. It is chiefly from the history of the case, and from the consideration of a variety of circumstances, that a correct diagnosis can be formed. Cancer most frequently commences in the cervix, and extends to the body of the organ. But in both situations it is either latent, or it does not come before the physician until it has made considerable progress. It is then, or it soon becomes, immovable, owing to adhesions between the uterus and surrounding tissues. "In chronic metritis there may be adhesions, but they are not of the perfectly immovable nature of those observed in the malignant affection. In cancer, the nodosities and inequalities are sharp, knife-backed, irregular; in chronic metritis, they are spherical and regular in their irregularity. Cancerous tissues are seldom very sensitive to the touch, whereas it is the reverse with the inflamed uterus. Cancer has a tendency to progress and to pass through its periods in the course of a limited space of time, say one, two, or three years. The symptoms indicating the existence of chronic metritis, on the contrary, may generally be traced back for several years, and when recognised, the disease appears to remain nearly stationary, if left to itself. The consideration of these differences will also prevent cancer being mistaken for chronic metritis. If cancer of the uterus has become ulcerated, the distinction is still plainer." (*Op. cit.*, p. 44.)

69. *D. ENLARGEMENT OF THE BODY OF THE UTERUS.*—Hypertrophy, or overgrowth of the uterus, more especially of its body, may in many cases be traced back for weeks or months to an abortion, or a severe labour, or to disease after delivery. It may, however, originate independently of any of the puerperal states. But in most circumstances it commences without marked severity, generally with slight ailment only, and

even when supervening upon abortion or delivery, it manifests merely a state of incomplete convalescence. When inflammation in any form follows either abortion or delivery, the process by which the womb is restored in a few weeks to its condition previously to conception—the *process of Involution*, as termed by ROKITSKY and WEST—is checked. This process takes place in the structure of the uterus, which, having performed its grand function, undergoes a state of degeneration, and a partial conversion into a fatty matter, rendering it more susceptible of being either absorbed or eliminated in the lochia. During the second week after parturition this process is most active; but it proceeds also during the third and even fourth week. The process of reconstruction soon follows, and, according to the German microscopists, cells, nuclei, caudate cells, and the elements of new fibres are formed, and the organ is built up anew. The manner of this reconstruction has not been satisfactorily explained by histologists; but it appears most probable that this renewal goes on *pari passu* with the removal of the old materials. The interior of the uterus undergoes similar changes to those which take place in its substance. "It is not until its lining membrane, with the exception of that of the cervix, has been several times reproduced and then cast off in a state of fatty degeneration, that it resumes the same condition as before impregnation. The occurrence of inflammation appears to interrupt these processes, for, though fatty degeneration of the tissues takes place, yet the removal of the useless material is but imperfectly accomplished, while the elements of the new uterus are themselves, as soon as produced, subjected to the same alteration; and the organ remains, long after the mischief has passed away, increased in size, and, at the same time, composed of a tissue inapt for all the physiological processes of conception, pregnancy, and child-bearing." (WEST, *Lect.*, p. 92.) This result will follow not only the mild, or chronic, or sub-acute states of inflammatory action developed in the organ during the process of involution, but even any excitement of the sexual organs occasioning determination of blood to the organ, more especially sexual intercourse too soon after delivery or abortion.

70. *Symptoms, &c.*—Enlargement of the uterus consequent upon *deficient involution* may continue a considerable time without causing more at first than protracted convalescence, and a feeling of local and general ailment; but generally farther disorder ensues, often with increased organic lesion. A sense of weight and bearing down; pains deep in the pelvis, back, and sacrum, often extending to the hips and thighs, numbness or pains in the limbs; difficult and painful defæcation, frequent micturition, &c., are usually complained of. After a time various complications of this lesion occur, more especially prolapsus, retroversion, congestion or chronic inflammation, frequent, or difficult, or excessive menstruation, &c.

71 *True hypertrophy*, or enlargement of the uterus independently of defective involution, occurs in both married and unmarried females. Dr. WEST considers that it is met with in the former chiefly, and remarks that "excessive or immoderate sexual intercourse does not produce it, though that leads to its own train of evils; but there has in many instances seemed good reason for associating the condition with the imperfect

performance of that function, and sometimes the evidences of that being the case have been conclusive." There can be no doubt of this being a not infrequent cause, although it is not the only organic lesion consequent upon this cause, ovarian disease being perhaps an equally frequent result. Although true or primary hypertrophy of the uterus may be most frequent in married females, it is by no means rare in the unmarried, especially after twenty-six or twenty-eight years of age, where there is reason to infer that the vice of masturbation has been long practised. It is in this class, as well as in widows, and in married women who have either impotent or nearly impotent husbands, a consequence of frequently-excited and imperfectly-gratified desire. Sexual intercourse is imperfectly performed, and although frequently attempted, never duly consummated; and thus congestion of, or active vascular determination to, the uterus is maintained, without conception and its successive changes taking place, whereby the mischief resulting from reiterated and inefficient sexual efforts is prevented. Hypertrophy of the *neck* of the uterus has already been noticed (§ 30, 31). Enlargements which result from the development of tumours in the organ are more appropriately considered in the sequel.\*

72. iii. INFLAMMATION AND ABSCESS OF THE FALLOPIAN TUBES AND CELLULAR TISSUE.—Inflammation and abscess of the uterine appendages were, until recently, described only as a disease of the puerperal state. Under the head *OVARIA*, I have considered inflammation and other diseases of these organs, independently of the puerperal state; and in the article on *PUERPERAL DISEASES*, "*Puerperal Inflammations of the Uterine Appendages*" have received due attention (§ 187, *et seq.*). It now only remains for me to describe *inflammation and abscess of the Fallopiian Tubes and Cellular Tissues, independently of the puerperal conditions*. This disease has been noticed by MM. GENDRIN, VELPEAU, MARÉCHAL DE CALVI, and by Dr. DOHERTY, CHURCHILL, and LEVER; but it was not fully discussed until Dr.

\* Inasmuch as both hypertrophy and atrophy of the uterus are, in part, normal at the periods of puberty and involution, there is some danger of confounding morbid with the healthy conditions of the organ. Like other organs, the weight and dimensions of the adult, healthy uterus fluctuate considerably. The following measurements will be found sufficiently accurate: Entire length, from 24 to 26 lines; greatest breadth, 18 lines; thickness, 9 lines; cervix, from 10 to 12 lines long; its breadth, from 6 to 8; its thickness, from 5 to 6 lines; length of uterine cavity, 12 lines; its breadth, 9 lines; greatest thickness of the fundus, 5 lines; of the sides, 4 lines; of the cervix, 3 lines. After one or more births, all these measurements increase from one fifth to one quarter. The weight of the uterus varies from 8 to 12 drachms, and may, after several pregnancies, amount to two ounces. Hypertrophy or atrophy may involve the whole or only a part of the organ. An atrophic condition is probably a frequent source of sterility; the organ, and especially the cervix, is small and anæmic, its tissue dense, and the ovaries in an equally undeveloped condition. After the climacteric period the cervix often disappears entirely, and nothing but an indurated ring remains at the summit of the vagina. We meet with hypertrophy of the uterus as a morbid state more frequently than atrophy, partly the result of irritation set up by other morbid processes, and partly as an exaggerated expression of the normal condition. The former may consist in fibrous or other tumours, involving the substance or cavity of the uterus, which may give rise eventually to expulsive efforts, or blenorrhagic affections of the mucous surfaces. Disease of the ovaries may also give rise to it by the consensual irritation thus set up. Where hypertrophy is confined to the cervix, the anterior lip is more frequently enlarged than the posterior.]

HENRY BENNET directed due attention to it in his work on *Inflammation of the Uterus and Appendages*. This malady in the puerperal states is always severe and generally dangerous; but in the non-puerperal conditions it is commonly much more mild, and is often either not recognised or confounded with other diseases. Indeed, inflammation of the uterine appendages occurring after parturition presents as great difference from the same disease in the ordinary state of the system as puerperal metritis offers to non-puerperal metritis. In the puerperal states of these maladies, as I have shown, inflammations of the womb, ovaries, Fallopian tubes, cellular tissues, &c., have a tendency to extend to the peritoneum, or to diffuse themselves, and produce most important and often fatal consecutive changes. But in the non-puerperal form, there is a tendency to assume the sthenic instead of the asthenic diathesis, and to limit itself to the tissues primarily attacked; peritonitis and other consecutive or fatal alterations rarely occurring.

73. *a.* The causes of non-puerperal inflammation of the Fallopian tubes are the same as those which more commonly produce metritis (§ 10, 22) and ovaritis (§ 6, *et seq.*); especially arrested menstruation, disordered states of this function, and abortive impregnation.

74. The inflammation may originate either in the cellular tissue, in the ovaries, in the tubes, or in the uterus, the disease of the one structure often extending more or less to the others. This extension of inflammatory action from the one part to the rest and to the peritoneum is most remarkable in the puerperal states (*see* OVARIA, § 6, *et seq.*, art. PUERPERAL DISEASE, § 181, *et seq.*), but it is much less so in the non-puerperal condition, the disease being generally limited to the cellular tissue, and to the organs contained between the folds of the peritoneum, this surface seldom being implicated in this condition. Dr. H. BENNET states that he has repeatedly seen inflammation of the Fallopian tubes supervene in females labouring under chronic inflammation or ulceration of the cervix uteri, this latter being the point of departure of the inflammatory action.

75. *b.* The symptoms of non-puerperal inflammation of the uterine appendages are nearly the same as those of acute metritis (§ 53). These are the usual febrile phenomena: severe pains in the lower hypogastric region, increased on stretching the body to the erect posture, or on walking; a sense of weight and tenderness deep in the pelvis; difficult or painful micturition and defæcation, &c. These symptoms are also present in metritis; but the pain is greatest in the ovarian region, to the right or left of the median line, where, if the ovarium be much affected, some degree of swelling may be perceived. So nearly, as may be expected, does the one disease approach to the other in characters and course, that, unless there be from the first a deep-seated tumour of an inflammatory nature perceptible in one or both ovarian regions on external pressure, it is most difficult to distinguish the one malady from the other by any other means than by a careful digital examination. The bladder having been emptied, the patient placed on her back, and the knees flexed, the finger should be passed into the vagina, and carried underneath and round the cervix, the left hand being firmly applied over the hypogastric region, above the pubis. By pushing the vaginal cul de sac by the finger in the several

directions around the cervix, especially while external pressure is being made, the presence of inflammation of the cellular tissue, ovaries, and Fallopian tubes, or of its consequences, is evinced by an unusual resistance on the side or sides of the uterus. "The vaginal cul de sac has disappeared, and resting on the side of the cervix and body of the uterus, there is an indurated swelling, very different from the normal condition, and from what obtains on the other or healthy side, supposing disease to exist on one side only, as is most frequently the case. Pressure on the indurated parts is attended by very great pain, and there is a marked increase of the natural heat." By directing the finger around the inflammatory tumour, while the left hand is pressed downward, the tumour is found to be movable and distinct from the parietes of the pelvis. This tumour being generally situated close to the side of the uterus, seems to form one mass with this organ. Hence inflammation of the lateral ligaments may be confounded with metritis even when a vaginal examination is resorted to, and an inflammatory swelling recognised. If this examination should not be satisfactory, the uterus and appendages may be farther examined per anum. Dr. H. BENNET believes that a tumour formed by an inflamed lateral ligament is more intimately connected with the uterus when it is purely phlegmonous, or the result of inflammation of the cellular tissue, than when it is formed by the inflamed ovary. It is, however, very difficult to distinguish between these and acute or chronic metritis.

76. *c. Progress and Terminations* — In the acute stage, inflammation of the lateral ligaments is attended by the usual train of febrile symptoms. As it passes into a chronic state, it occasions numerous morbid phenomena, which have been noticed as characterizing other chronic uterine diseases, especially dyspepsia, cephalalgia, constipation, palpitation, insomnia, debility, emaciation, evening exacerbations of fever, &c. It may terminate in resolution in the first stage, when promptly and judiciously treated; but, unlike metritis, which very rarely, in the non-puerperal state, terminates in suppuration, inflammation of the Fallopian tubes, especially when seated chiefly in the cellular tissue, generally ends in suppuration—it being purely phlegmonous inflammation.

77. *d. Suppuration* may be expected in the course of a few days from the commencement of the inflammation, unless checked by early and energetic treatment. The occurrence of rigors, followed by sweats, and a temporary abatement of the more acute symptoms, and sometimes a deep-seated fluctuation perceptible to the touch through the vagina, or even through the abdominal parietes, indicate the presence of suppuration. The purulent collection in this part is rarely absorbed; but it generally finds an exit, before the acute inflammatory symptoms have subsided. Adhesive inflammation connects the abscess with either the vagina, rectum, abdominal parietes, or bladder, the contained pus making its way after a variable period in one or other of these directions, most frequently in the upper part of the vagina, or in the rectum. It very rarely opens into the bladder or abdominal parietes. It sometimes opens in more than one situation successively. The abscess may, however, ulcerate through the peritoneal folds of the lateral ligament, and be evacuated into the peritoneum, causing acute peritonitis; or "the purulent mat-

ter may pass along the round ligament and appear in the labia externa, or, escaping from the pelvis along with the large femoral vessels, follow their course, and point in the thigh. These, however, are quite exceptional cases, and are very rarely met with, especially in the non-puerperal form of the disease."

78 *e.* The abscess generally opens into the vagina or rectum, or into both. The perforation commonly occurs during exertion, or when coughing, or in the act of defæcation; and the purulent discharge is very frequently either mistaken for an increased flow of the whites, or overlooked when it is passed from the rectum with the stools. This usually obtains when the disease is either not recognised, or viewed as metritis. In some cases, the perforation is attended by a sense of bursting. The discharge may take place a few days after the development of the inflammation, or not until after several weeks. The quantity of pus discharged varies from a few drachms to half a pint. The opening of the abscess into the vagina is the most favourable issue that can occur. The pus occasions some irritation of the vagina, but this is seldom considerable. The opening of the abscess into the rectum is the next most favourable termination, but it generally causes considerable irritation of this bowel, with dysenteric stools or tenesmus. The perforation of the bladder or of the abdominal parietes by the abscess is so rare, and the occurrence so manifest, that the phenomena attending it require no remark, farther than that, as in the case of the rectum, the urine does not pass through the opening, owing to the pressure of the abdominal organs keeping the opening closed.

79. When the pus is discharged, a decided lull is observed in all the symptoms. The deep-seated pains, the tenderness and swelling, and the febrile disturbance rapidly subside. When the abscess has opened into the vagina, the improvement is often rapid, and the patient is believed to be convalescent. But, as Dr. H. BENNET justly observes, this improvement is often deceptive, with reference to the future. On making a careful examination, the tumour on the side of the uterus is diminished in size, and is much less sensitive to the touch; but, although less in size and less inflamed, it is nearly always still perceptible; and the symptoms indicating chronic uterine inflammation generally exist; pain, heaviness, bearing down, tenderness, often swelling in one or both ovarian regions; pain in the back, inability to stand erect, or to walk for any time, or to go up and down stairs, being complained of. The orifice by which the pus was discharged may remain open, or it may close. In the former case the pus escapes as it is formed, and after some time it becomes closed, and the tumour is resolved, the disease being brought to a close in the course of a few weeks, or of a month or two. This, however, occurs only in some cases; for in others the closing of the orifice is followed by a re-formation of the abscess; and before it again escapes, by the former or another opening, the acute inflammatory symptoms previously experienced are reproduced, generally in a mitigated form. The vascular determination attending menstruation favours the reappearance of acute symptoms, and thereby perpetuates the disease. These returns of the malady become less and less frequent as the inflammatory swelling of the uterine appendages diminishes, and as the struc-

turés return to their natural condition. "A female who has suffered inflammation and suppuration of the lateral ligaments, even in its mildest form, may be from several months to one or more years before all trace of local inflammation has disappeared, and before she can be said to be radically well." During this period she is never quite free from symptoms of uterine irritation, or of slight exacerbations of her former malady, especially at the menstrual periods, which are often delayed or irregular; the quantity of discharge being generally scanty, seldom excessive. A leucorrhæal discharge is always present, in various quantity. (*See Puerperal Diseases*, § 181, *et seq.*)

80. *f.* The Prognosis of this disease in the non-puerperal state is not serious as regards the life of the patient: in the puerperal state it is much more serious (*see Puerperal Diseases*, § 183, and 256, *et seq.*), and often most unfavourable. Apart from this state, this disease seldom terminates fatally, although it entails suffering for months or even for years. Acute metritis generally terminates by resolution, under judicious treatment (§ 111, *et seq.*), without suppuration, and without consecutive lesion; but inflammation of the lateral ligaments, although apparently not a more severe disease at its commencement, and period of full development, occasions lesions which time only can remove, or which are never completely removed.

81. *iv.* ASSOCIATIONS OR COMPLICATIONS OF INFLAMMATIONS OF THE UTERUS, &c.—Inflammation of the vagina and vulva may be associated with inflammation of the neck of the uterus, or even with internal or endo-metritis also; and the inflammation may commence either in the vulva or vagina, and extend to the neck of the womb, or in this latter, and extend to the former. In cases of *gonorrhæal inflammation* of the neck of the womb, it may be inferred that the inflammation commences most frequently in the vulva and vagina; but such may not always be the case; for it is not improbable that the neck of the uterus is sometimes primarily affected. In the cases, fortunately rare, in which septic or contaminating causes produce an asthenic or diffusive form of vaginitis, as well as in gonorrhæal inflammation, the disease is always prone to extend from the neck to the internal surface of the womb, and even also to the uterine appendages.

82. Various derangements of the uterus, formerly considered as functional, are in most cases merely symptoms or associations of inflammation of the cervix and internal surface of the uterus, as Dr. H. BENNET has fully succeeded in demonstrating, and as I have stated to be the case in several forms of LEUCORRŒA, and of disordered MENSTRUATION. The leucorrhæal discharge varies with the tissue affected and the nature of the affection. It may consist of natural mucus from the mucous follicles of the vulva, vagina, and cervix uteri; of a white creamy mucus secreted by the mucous membrane of the cervix and vagina, from congestion of this membrane, such congestion not always amounting to disease; and of a puriform mucus, or a white or ropy transparent mucus mixed with pus, which is always the product of inflammatory action and of its consequences. These three forms of vaginal discharge may be combined in chronic inflammation of the cervix. But this disease may exist without any leucorrhæal discharge whatever, the morbid se-

cretions being absorbed in the vagina. (See *art. LEUCORRŒA*, § 19, *et seq.*)

83. Amenorrhœa and other menstrual disorders are often consequences or complications of uterine inflammations. Dysmenorrhœa is very frequently a result of inflammation of the cervix uteri; and when thus associated, other disorders are often superinduced, more especially the several states of, hysteria, convulsive affections, spinal irritation, &c. The changes which take place in the cervix and its canal, in consequence of inflammation or ulceration of them, are often such as occasion difficult menstruation as the consequence of contraction of the os internum, or of the canal which forms the cavity of the cervix. The swelling and hypertrophy of the cervix are frequently associated with this contraction, when the cervical canal itself is not the chief seat of inflammation. Dr. SIMPSON believes that, unless the uterine sound pass, without effort, into the uterine cavity, there is contraction of the os internum; while Dr. HENRY BENNET contends that there exists, at the os internum, a kind of muscular sphincter, formed by a strong band of the circular muscular fibres of the cervix, and destined to close the uterus during pregnancy; and that this sphincter in the healthy state prevents the uterine sound from passing into the uterus without considerable pressure be made; and he adds, that when the inflammation of the cervix ascends as far as the os internum, or when endo-metritis exists, or the organ is enlarged by the formation of tumours in its body, then the sound passes readily into the uterine cavity, thereby furnishing a sign of the presence of these diseases.

84. It has been considered that *menorrhagia* and *uterine hæmorrhage* generally are results of active or passive congestion, or of tumours or polypi, or of malignant disease, of the womb. Dr. HENRY BENNET, however, contends, and with apparently much truth as well as talent, that, in the absence of malignant disease and of uterine tumours, the quantity of blood lost during menstruation is seldom increased, for a continuance, so as to constitute menorrhagia, and that the menstrual periods are seldom morbidly approximated, unless there exist some degree of chronic inflammatory disease of the cervix, or unless menstruation be finally disappearing. Congestion of the uterus he admits to exist in menorrhagia, but it is generally the result of inflammation of the cervix; and it assumes an active or passive character, according to the constitution of the patient, and to the amount of reaction produced by the disease on the system. If the inflammation is active and has not debilitated the patient, the hæmorrhage is also active or sthenic. If the disease of the cervix has existed long, and has produced anæmia or debility, the hæmorrhage is passive or asthenic. It is difficult to explain the reason why inflammation, granulation, or ulceration of the cervix should, in some cases, render menstruation scanty, too rare, or difficult, and in others profuse or too frequent. But the fact is proved by observation, and it may be referred to the states of innervation of the uterine organs in different persons, and to the sympathies exerted between this very sensitive part of the uterine organs, in connexion with the vascular conditions of these organs, and of the system generally. Dr. BENNET, however, believes that, where the inflammation extends to the body of the womb, menstruation is generally scanty or retarded;

whereas, when it is limited to the cervix, it is often profuse or more frequent than usual. Although this association of inflammation of the cervix uteri with disordered menstruation is so common, as now stated, still cases occur in which this latter must be referred to other pathological sources. Indeed profuse menstruation is occasionally produced by mere congestion or determination of blood to the uterus, independently of the existence of inflammation of the cervix, especially when the catamenia are finally disappearing. The association of inflammatory ulceration of the cervix uteri with hæmorrhage during pregnancy, in the opinion of Dr. H. BENNET, very frequently exists; the former being the source of the latter, and thus furnishing a natural explanation of the presumed menstruation of pregnant females.

85. That chronic inflammation of the neck and of the body of the uterus should occasion, and be associated with, *sterility*, with *abortion*, with *hysteria*, in its several forms; with *spinal irritation*, with *chlorosis*, and with various anomalous *neuralgic* and other *affections*, in different cases, according to the circumstances peculiar to the individual, cannot be doubted, although the relation between it and these ailments was overlooked until Dr. H. BENNET and some contemporary physicians, British and continental, insisted upon the fact of its frequent existence. Besides the complications of this disease with these complaints, the former is often associated with other lesions of the uterus itself and its appendages, as with *enlargements*, *polypi*, and *fibrous tumours* of the womb; with the various forms of *displacement* of the organ, with *lesions* of the *ovaria*, and with *uterine phlebitis*.

86. Besides the above associations, others affecting the adjoining organs or parts are not infrequent, and are to be viewed as being much more frequently consequent upon chronic inflammation of the cervix and body of the uterus, than existing as the primary affections. Inflammation of the urinary bladder, or of the rectum and sigmoid flexure of the colon, more especially of their mucous surfaces; hæmorrhoids, and prolapsus or fissures of the anus, and syphilitic disease of the cervix uteri, severally occur as complications of one or other of the forms of metritis. Of these the diseases of the rectum and urinary bladder are chiefly consequences of the extension of severe or protracted inflammation of the cervix and body of the womb, sometimes extending also to the uterine appendages, these latter, in a few instances, being the medium of morbid connexion between the different maladies. It is comparatively more rare for disease of the large bowels, or of the bladder, to occasion any of the forms of metritis, than for this last to cause, by the extension of inflammatory action, one or other of the former. Yet I have seen instances, in the non-puerperal states, of metritis which had supervened on dysentery, and even of asthenic inflammation, that had extended to most of the pelvic viscera, consequent upon a dysenteric attack. Such complications as these are, however, much more frequent and fatal in the puerperal states; and in these the veins are also very commonly implicated. This complication of metritis with uterine phlebitis may occur even in the non-puerperal state, as I have seen in a few instances. In a very remarkable case of this kind, which was seen in consultation with me by Dr. R. LEE,

metritis supervened upon dysentery in a married lady, aged about 35 years, and who had not been pregnant for several years. Uterine phlebitis also took place, and was followed by phlegmasia dolens. Inflammation of the cæcum and pericæcal tissues may extend to the uterus and uterine appendages; but this is a very rare occurrence.

87. III. TREATMENT OF INFLAMMATIONS OF THE UTERUS AND APPENDAGES.—Much of what I have stated above respecting the treatment of the nervous and irritable states of the womb (see § 13, *et seq.*) is applicable to inflammatory action in either the cervix or body of the organ. It is manifest that, as the several inflammatory states of the uterus, whatever may be their precise seats, occur in the nervous, the debilitated, the anæmied, as well as in the plethoric and the robust, the treatment, especially the general or constitutional, must depend in great measure on the knowledge, acumen, and experience of the physician, by which he is enabled to ascertain the precise peculiarities of each case. A most important part, however, of the treatment is entirely local or surgical; but, in the management of female diseases, no division should be made into medical and surgical means, for here, as in all other departments of practice, surgery, although ancillary to, is also a part of, medicine.

88. I. OF INFLAMMATION OF THE NECK OF THE WOMB, AND ITS CONSEQUENCES.—There are few complaints more prone to relapse, and in its severer states more difficult to remove, than the one now under consideration. But these are not the only evils; the difficulty often of conducting the treatment conformably with the requirements of the case and the prepossessions of the patient, is also a positive obstacle to success, particularly in females whose circumstances of life require exertion, or prevent them from enjoying the requisite comfort and ease, and in unmarried females. The treatment must necessarily depend upon the peculiarities of the case, with what is known or inferred as to its causes, upon the duration of the disease, and upon the alterations which have taken place in the part. But in this, as well as in all other inflammations of the uterus, the *indications of cure* consist, *first*, in subduing inflammatory action and painful symptoms; and, *second*, in restoring the constitutional energies, and thereby the healthy state of the uterus. It often becomes a great difficulty to know when to discontinue the first indication, and when to aim at the second; for a too early adoption of means calculated to restore the health may occasion a relapse of inflammatory action and its attendants.

89. A. *The treatment before any organic lesions have taken place*, and while inflammatory action is unassociated, comprises the two *intentions of cure* just stated (§ 83). The means which are found most successful in fulfilling the *first* intention are the horizontal posture, and quietude of mind and body; injections of an emollient, refrigerant, or anodyne kind; cooling diaphoretics, with or without narcotics, warm or tepid hip-baths, local depletions, alterants, and sometimes derivatives. This state of the disease, especially at its commencement, is so often unattended by severe symptoms, unless when it is associated with the neuralgic and irritable conditions described above (see § 5, *et seq.*), that it seldom comes under medical care; and it is not, commonly, until either excoriations, granulations, or superficial ulcerations, very frequently associated

with *leucorrhæa*, *disordered menstruations*, and *deviations* from the natural position of the womb, that medical aid is resorted to. In all cases, due care should be taken to ascertain the admitted and probable *causes* of the complaint. It will be seen, on referring to these causes (see § 10), that certain of them can hardly be fully ascertained, although they may be inferred with a near approach to certainty; and in some cases they will be admitted by the patient, if inquiries be made with due address. The state of general health should also receive attention, and the treatment be regulated accordingly, and with strict reference to the condition and periods of the uterine functions.

In the *mild cases*, if they have not been of long duration, and if the cause have been only temporary in its operation, and not a persistent or habitual vice, means directed to the improvement of the general health, to the regulation and promotion of the secretions and excretions, more particularly to the prevention of fecal and urinous accumulations, aided by rest, the avoidance of sexual excitement, and by emollient and astringent or refrigerant injections, according to the peculiarities of the case, will be sufficient to restore the health, even without strict reference to the succession of indications of cure mentioned above (§ 88).

90. In *severe cases*, especially in those of long duration, and in those where the above means fail of affording satisfactory relief, the indications of cure stated above should be adopted, more particularly if thickening or enlargement of the cervix or any other of the lesions described as consequences of chronic inflammation be present. For these the means enumerated for fulfilling the *first* indication should be prescribed. For this purpose, constant repose on a couch or sofa, avoiding very warm beds, and the upright or even the sitting posture, vaginal injections, hip-baths, local vascular depletions, and a recourse to caustics, are the means of cure now in general use. But, although the chief remedies, they are not the only ones; and in all cases they should be aided by constitutional and moral treatment, by a proper diet and regimen, if, indeed, the local remedies be not considered as being aids only to the constitutional means. These latter require to be so diversified, according to the temperament, habit of body, strength, and other peculiarities of the case, that a selection of them appropriately to these peculiarities must depend upon the judgment of the physician.

91. a. *Vaginal injections* are often of great service, whether *simple* or *medicated*. They wash away the secretion from the inflamed cervix, and prevent the stagnation of it in the vagina and around the cervix; an occurrence tending to increase irritation and morbid sensibility of the parts. The frequent injection of *cold water* only has not only a cleansing, but also a tonic and healing effect. In some cases the temperature of the water may be heightened somewhat above fifty degrees of Fahrenheit. But in most cases the temperature of spring water is best, the quantity injected, or the duration of the injection, being regulated by the physician.

92. *Medicated injections* are either emollient, astringent, or anodyne. Various emollient injections are of service in slighter cases, and when pain or irritation is experienced; and they may be made vehicles for anodynes. Milk and wa-

ter, decoction of marsh-mallows, linsced tea, &c., may be used, cold or tepid. When irritation is considerable, a small quantity of the bi-borate of soda, or of any of the anodynes, especially vinum opii, tincture of henbane, or tincture of belladonna, may then be added to the above. Injections also of the decoction of poppy-heads, either alone or with chamomile flowers, may be prescribed. Astringent injections are very commonly resorted to in this complaint, especially when the discharge is abundant. In this and the above cases, the means advised for the treatment of *LEUCORRHEA* (see § 16, 17), and of that state of the disease especially which I have ascribed to "*inflammatory action of the mucous glands of the cervix and os uteri*" (§ 23, 24), are quite appropriate. Of the several astringent injections in common use, viz., sulphate of alumina, sulphate of zinc, acetate of lead, solution of nitrate of silver, decoction of oak bark, and solution of tannin, Dr. H. BENNET states that he prefers the first and the solution of nitrate of silver. The first three he uses in the proportion of a drachm to a pint of water, increasing or diminishing the strength according to circumstances. He, however, considers that injections are serviceable chiefly for cleansing the vagina, for diminishing uterine irritation, and for removing vaginal and vulvar inflammation; but that they are generally powerless to subdue confirmed inflammation of the substance of the cervix, or even of the membrane lining its cavity; for he believes that their inefficacy in inflammation of the cervical canal is partly owing to the fluid not reaching the region affected; and that in inflammation of the cervix, a remedy which is only applied to the surface can scarcely be expected to subdue the deep-seated disease. When injections are prescribed, due care should be taken that they are properly administered. The patient should be on her back, with the pelvis raised, and means be used for their retention for a time in the upper part of the vagina.

93. When marked irritability and acute sensibility characterize inflammatory action of the cervix, Dr. DEWEES recommends lukewarm flaxseed tea, to be thrown up by a female syringe of sufficient size three or four times a day, and to be retained there for some time by applying a cloth to the vulva. I have more frequently prescribed, especially for unmarried females, in order to remove the more painful symptoms, injections into the rectum, containing either the extract or the sirup of poppies, or compound tincture of camphor, or vinum opii, or tincture of henbane. In a case of remarkable severity which I attended with the late Dr. MOORE, a small quantity of tincture of belladonna was pressed from a piece of sponge contained in a syringe, when introduced as far as the cervix uteri, and always afforded immediate relief.

94 *b Baths*.—Warm *hip-baths* at the temperature of 90° are occasionally of service. Dr. J. H. BENNET advises them at a temperature of 63° to 85° Fahrenheit, according to the season of the year and feelings of the patient. At this temperature they have a sedative effect, while at higher degrees he believes that they determine the circulation to the pelvis. In painful or difficult menstruation, a temperature of 94° to 98° is often decidedly beneficial. Dr. GOOCH states that he has found a partial steam-bath, used by drawing the flannel sack up to the præcordia, so as to enclose

the abdomen and extremities, these being exposed to the action of the steam for half an hour every day, preferable to the warm hip-bath. Entire warm baths are useful in winter, when only occasionally resorted to, and when they can be had in the patient's house or apartment. During summer a tepid bath at 65° or 70° is of service every second, or third, or fourth day. Cold and shower baths should be reserved for advanced convalescence, and are important means for fulfilling the second intention of cure.

95. *c. Vascular Depletions*.—These should be chiefly local; and, with all respect for those who cultivate this specialty, I cannot agree with them in the choice of situation from which the blood should be abstracted. The situation preferred by the more recent writers on diseases of the uterus is the inflamed cervix itself; but the several difficulties in the way of the general physician, if he be averse to the manipulation which this practice involves, and if he have due regard to the feelings of the patient, and even in some cases to sentiments of virgin purity, will induce him to choose other situations than this one from which blood may, in this disease, be abstracted with advantage, and to have recourse to other and various means by which the end in view may be accomplished. I know that in all cases where this and other appliances to the neck of the womb are resorted to by physicians who practise in this especial department the utmost attentions are paid by them to the modest feelings of the patient, and to all decent, and even delicate observances; but I should prefer having recourse, in the first place, to such means as cannot be objected to by the sensitive mind, or even by the captious; and leave such measures as may become matters of reproach to both the patient and physician, although most unjustly, to the necessities of the case—as a *dernier ressort* in practice. I may write under prejudice in favour of older modes of practice, for I have employed these and seen the benefits they afford, when judiciously employed and combined; but I nevertheless admit that the measures more recently had recourse to are often more quickly successful, and sometimes succeed after the others have failed.

96. Local abstractions of blood should be directed as near as possible to the seat of pain. Cupping is more serviceable than leeches, particularly when the pulse is full or firm, and the patient not reduced. In these cases, or when the patient is young and plethoric, or when the menstrual discharge has been scanty for some time previously, a general depletion will be advantageously premised, and more especially when the blood is taken from the feet when immersed in warm water. When pain is referred to the sacrum, cupping may be directed on this part. Leeches are generally most beneficial when applied to the vicinity of the anus, or the labia pudendæ, or to the inner parts of the tops of the thighs just below the vulva or groins. The quantity of blood that may be taken away should depend upon the habit of body, the state of the circulation, and on the severity and duration of the complaint. My objections to the application of leeches to the cervix uteri are, 1st, those already hinted at above, and particularly in respect of unmarried females; and, 2d, the risk of the application of them to this part being followed by an excessive determination of blood to the organ, or by ulceration of their bites, and consequently

increased irritation. It will, however, be admitted that these are contingencies which may seldom occur; nevertheless, they should not be hazarded.

97. The repetition of local depletion should necessarily depend upon the effect of the previous operation, and upon the circumstances just mentioned. In cases of long continuance, when the constitution is much enfeebled, even local depletion is but ill borne, and should seldom exceed from four to six ounces. In these its repetition is rarely attended with much advantage. But when the repetition seems required and gives relief, it should generally be to a smaller amount than the first, and be performed at a time when the return or increase of pain is anticipated. In this way it may be repeated thrice, or even more frequently, to the small amount now named. There are, however, instances where even a small local depletion aggravates the symptoms. These occur chiefly in weak, nervous, or anæmied females, and in cases of long standing, or where the leucorrhœal discharge has been long profuse. In this class of patients the *second indication* of cure (§ 88) should be immediately adopted.

98. Dr. HENRY BENNET remarks that the application of leeches to the cervix uteri, when often repeated, is more frequently injurious than beneficial, and that the consequences mentioned above then frequently result from them. I must, however, refer the reader to his work for many judicious observations respecting the local employment of leeches in this disease. Dr. WEST states that, "so long as acute symptoms are present, or whenever they reappear in the chronic stage of the disorder, local leeching generally affords more speedy and more decided relief than other remedial means. The leeches should be applied to the uterus itself; not above four in number at a time; nor is it in general expedient to repeat their application above once in a week or ten days. Another precaution consists in never leeching the womb within four or five days of a menstrual period; lest the regularity of that function be disturbed, either by being brought on prematurely or (which is much less frequent) by its occurrence being postponed for several days. The pain which is left behind after menstruation in some of these cases—in those especially in which the discharge is scanty—is, however, often very greatly relieved by the application of a few leeches as the period passes off." (*Lect.*, p. 140.)

99. *d. Cooling aperients* are generally required both at the commencement and during the course of treatment, owing to the state of the bowels and to the effects of narcotics taken from time to time. Those aperients which will operate copiously once, or twice at most, and without irritating the lower bowels, are the most eligible. Castor oil, the elctuary or confection of senna, either alone or with sulphur and bi-tartrate of potash, will prove the most certain. In very chronic cases, or when the digestive organs and the system generally are much weakened, rhubarb and magnesia; or the compound infusions of gentian and senna, in equal parts, with tartrate of potash, tincture of henbane, and tincture of cardamoms, will be found of service.

100. *e. Narcotics or sedatives* are often required, not only in the injections, as advised above, but also in the medicines taken by the mouth, or ad-

ministered in enemata. They are most serviceable after a gentle action on the bowels has been produced. Camphor, in the dose of one or two grains, with the nitrate of potash and the extract either of henbane, or of hemlock, or of poppy, given in the form of pill twice or thrice daily, or about ten grains of either of these extracts, dissolved in water gruel and injected up the rectum, immediately after the bowels have acted, will frequently afford relief when much pain is experienced. Subsequently the bitter infusions may be prescribed with tincture of henbane, and small doses of nitrate of potash and bicarbonate of potash or of soda. These means also serve to diminish irritability of the bladder by which uterine inflammation is often attended. If deposits of the phosphates exist in the urine, small doses of hydrochloric acid, with tincture of henbane and extract of pareira, prescribed in the infusion of calumba, or of orange peel, generally are of service.

101. *f. External applications* of various kinds have been recommended, as the croton-oil liniment (one part of the oil to ten of simple camphor liniment), by Dr. WEST, to be applied over the sacrum by means of a sponge twice a day; in order to relieve the back-ache, plasters of opium or of belladonna, to the same situation, and with the same intention; and a small blister, or an anodyne liniment, applied over the part, when pain is urgent in either iliac region. Dr. OLDHAM advises the following in this latter situation:

No. 365. R Extracti Belladonnæ, ʒss.; Tinct. Aconiti (Fleming's), ʒiv.; Linimenti Saponis Comp., ʒjss. Misce. Fiat Linimentum.

In cases where pain either in the back, sacrum, or iliac regions is most severe, I have found more relief procured from an embrocation, frequently recommended in this work, consisting of equal parts of the compound camphor liniment, of the turpentine liniment, with variable proportions of sweet oil and cajuput oil, applied over the part on folds of flannel or spongiopiline, than from any other application. Warm turpentine stupes are also very beneficial.

102. *B. When inflammation of the uterus is attended by granulations, excoriations, ulceration, and hypertrophy of the cervix*, additional means to those already mentioned are recommended, especially by recent writers on uterine diseases. Dr. HENRY BENNET states, that the solid nitrate of silver, or a strong solution, should be applied every three or four days to the inflamed mucous membrane covering the cervix, where there is neither ulceration nor hypertrophy of this part; and this treatment should be the first resorted to when the cavity of the cervix is inflamed, "carrying the caustic into the cervical cavity as far as it will pass." When ulceration and hypertrophy of the neck of the uterus are present, he adds that the means already advised seldom succeed in effecting a cure, unless the ulceration be recent, although they mitigate the severer symptoms; a relapse occurring in a short time. Repeated relapses, and a perpetuation of ulceration of the cervix and cervical canal, are the consequences of palliation merely, owing to the repeated determination of blood to the uterus during the menstrual periods. Should the disease not yield (and it seldom does) to the antiphlogistic means directed as above, the most efficacious treatment, he remarks, "indeed the only one that can be depended upon, is by direct stimulation of the dis-

ceased and ulcerated surface, and to modify its vitality in such a manner as to induce a healthy action, and, finally, cicatrization. This end is obtained by the use of caustics of varied strength, according to the nature and extent of the disease, its chronicity, and the effects produced." "We must first subdue sub-acute inflammatory action by emollients, depletion, and astringents; and then modify, by direct stimulation, the diseased surface, so as to substitute healthy reparative inflammation for morbid ulcerative inflammation."

103. The last part to heal in an ulceration of the neck of the uterus is that which dips into the cervical cavity. Dr. BENNET therefore insists upon the necessity of separating the lips of the os with a bivalve speculum, in a good light, and of thus carefully exploring the state of the cervical canal before the disease is pronounced to be cured. Unless this precaution be used, the ulceration may be only partially cured, and the disease will return and extend over the cervix in a few months. The agents recommended for the cure of disease of the cervix—for chronic inflammation, excoriations, granulations, ulcerations, with or without enlargement, induration and deviations—are chiefly the more energetic caustics, which he enumerates in the order of their powers of cauterization: The solution of, and the solid nitrate of silver, the mineral acids, the acid nitrate of mercury, potassa fusa, potassa cum calce, and the actual cautery. It is obvious that a recourse to either of these requires both address and careful appliances. The nitrate of silver, acid nitrate of mercury, and potassa cum calce, are chiefly recommended by British writers on uterine diseases; these and the actual cautery also being much employed by French physicians. For very full directions for the use of these caustics, I must recommend the reader to the works of Dr. J. HENRY BENNET, Dr. SIMPSON, and of the other writers mentioned above; but as the directions given for the use of these means by Dr. WEST are more succinct, I shall give them nearly in his words; premising, however, that the able and experienced physicians now named generally have recourse to the more energetic of these caustics in the most severe and protracted cases, and when more or less hypertrophy of the cervix is associated with other lesions.

104. When the granulations on the os and cervix uteri become large, soft, very vascular, and bleed easily, the surface furnishing a copious glairy discharge, sexual intercourse being painful and often followed by bleeding, Dr. WEST then recommends "extensive scarifications, which may be followed by the daily application of powdered alum on a piece of cotton-wool, or by the introduction of a piece of cotton-wool soaked in a strong solution of alum. By means of a piece of thread tied to the cotton-wool, it can be removed by the patient herself in the course of a few hours, though it must always be introduced through the speculum. In the greater number of instances the state of the os uteri becomes so much improved in four or five days, that this mode of treatment may then be dispensed with, and the sedulous employment of strong astringent injections will usually suffice to complete the patient's cure. When this is not the case, but the morbid condition still continues, more powerful applications may be needed. The nitrate of silver is not in general suitable in these cases, for its application

is often followed by pain and also by bleeding. The acid nitrate of mercury, both in this instance and also whenever a strong caustic is required, has seemed the most useful application; and with moderate care its employment is unattended by risk. When it is used, however, the patient must lie on her back, and one of COXETER's bivalve speculums being introduced so as thoroughly to expose the os uteri and include the cervix, a little cotton-wool must be carefully disposed all round the edge of the speculum, so as to absorb any of the superfluous acid, and to prevent it from running down outside the speculum, and thus injuring the vagina. A brush can easily be extemporized by trimming a little piece of cotton-wool after it is placed in the holder, and the whole diseased surface may then be painted over with the caustic, which immediately forms upon it a white eschar. A piece of dry cotton-wool now pressed against the part will absorb any superfluous caustic; the little strips placed around the edges of the speculum may then be removed, and the speculum withdrawn." As an additional precaution, a piece of moistened cotton-wool may be introduced up to the os uteri, before the withdrawal of the speculum, whence it may be removed in the course of a few hours, by the patient. "It is seldom that either pain or bleeding follows this application; and at the end of a week the eschar will usually be separated; the surface will be found to have lost its fungous character, and cicatrization to be commencing at its edges. A zinc lotion of about five grains to the ounce, or the black wash employed as a vaginal injection twice a day, will now generally be sufficient; but sometimes the surface puts on an indolent character again, and it may then be expedient to touch it once or twice with the nitrate of silver, and I have occasionally found it necessary to repeat the application of the acid nitrate of mercury." (*Lect.* p. 146.) Dr. HENRY BENNET employs, as escharotics, either the acid nitrate of mercury, or the potassa cum calce, fused in sticks of three different sizes, according to the peculiarities of the local lesion; and gives ample directions for the use of these and other caustics, appropriately to the circumstances of the disease. He, however, admits that cauterization of the cervix is an operation not without danger, and must, therefore, be either injudiciously resorted to or carelessly carried out. Although his own "practice has been hitherto free, or all but free, from serious accidents, the same immunity cannot always be expected. Indeed, I recently learned from M. GENDRIN that within the last few years he has had several cases of acute metritis and of abscess in the lateral ligaments, the evident and immediate result of deep cauterization. But he also tells me that he has seen the same results follow the use of the nitrate of silver and of injections; and I may mention that the two most severe instances of acute metritis that I have myself witnessed for some time in the unimpregnated womb occurred after the use of weak astringent vaginal injections." (*Op. cit.*, p. 426.) I believe, however, when vaginal injections are followed by those severe results, that the inflammation of the cervix, or the leucorrhœa, for which these means were used, was only a part of the existing lesion; and that endo-metritis, or a chronic metritis, had also existed at the same time, and was developed into the acute state by the injections.

105. *C. Treatment of Hypertrophy and Induration of the Cervix Uteri.*—These changes are the results of repeated congestion, or of inflammatory congestion and of nutritive hypertrophy. The continued existence, or repeated recurrence of inflammatory congestion, gives rise to increased development of the vessels, to the exudation of plastic lymph, and to the partial organization of this lymph, and to greatly increased size and density of this part of the uterus, often extending partially to the substance of the uterus itself, and associated with *chronic metritis* (§ 62, *et seq.*). This lesion is commonly attended by more or less prolapsi, and often with deviations. The enlarged cervix may, moreover, be excoriated, ulcerated, or covered by granular formations, owing to the alterations of its follicles. The *local means* of cure are those already recommended, aided by the constitutional treatment hereafter to be noticed (§ 106, *et seq.*). Dr. H. BENNET states that, "if hypertrophy resists the ordinary antiphlogistic means of treatment, it never withstands the melting influence of deep cauterization with potassa, or the actual cautery." Of the two he prefers the potassa, or potassa eum calee; Dr. WEST the acid nitrate of mercury. The actual cautery may therefore be dismissed. It should be clearly understood that these means are not intended to destroy the hypertrophied cervix, "but merely to set up an artificial eliminatory inflammation, by means of an eschar or issue, of limited extent, established in the centre of the hypertrophied region. I do not calculate in the remotest degree on the destruction of tissue to which the caustic or cautery gives rise, for diminishing the size of the hypertrophied cervix, but solely and entirely on the *inflammation subsequently set up.*" An eschar of the size of a shilling will answer the purpose of reducing the hypertrophy. It may be necessary to apply the caustic several times. "The ulcerations occasioned by the deep application of potassa heal very rapidly, even when left to themselves. It is better, however, to touch them at intervals with the nitrate of silver, to prevent the granulations from becoming too luxuriant, and to favour the cicatrization, which usually takes place in from four to six weeks."

106. *D. Constitutional and general Treatment.*—The constitutional treatment of chronic inflammation of the cervix and os uteri, and its usual consequences, should not be overlooked, even while local means are being applied. Indeed, in many cases, this treatment should precede a recourse to local measures, these latter only following the failure of the former. In some of the more recent works upon this and other diseases of the uterus, too little importance is attached to the recognition of the causes of the existing malady, and upon the prevention and removal of these causes, which, when removed, the salutary efforts of nature would then of themselves often effect a cure. In this disease especially, as well as in the displacements and deviations of the uterus, sexual excitement and self-pollution are the most frequent causes, and these are usually allowed to continue, owing to the difficulty and delicacy of the subject, to ignorance of medical men of the great frequency of this vice, and to an equal ignorance of the immorality and injurious consequences of it on the part of those who indulge in it.

107. The constitutional treatment which I have adopted for many years, when uterine irritation, as it was then termed, or when chronic inflamma-

tory irritation, as more recently shown, was present, always was much modified, according to the features of the case. If *leucorrhœa* was its prominent character, the means advised when treating of this complaint were prescribed. If the *menstrual function* was disordered, the treatment recommended for the various forms of such disorder was had recourse to; and, whenever inflammatory irritation of the uterus was inferred, then means more or less antiphlogistic were advised, often conjoined with tonics, and with other remedies adapted to the peculiarities of the case. In a very large proportion of the cases of this complaint, the causes which have produced it, and the discharges which characterize it, as well as its exhausting nature and duration, have produced so much debility and irritability, and so extensive a range of sympathetic disorders—nervous, neuralgic, hysterical, cerebro-spinal, vascular, and anæmic—as to imperatively require constitutional treatment, however much the local means above described may be required or confided in. What this treatment should be, or how conjoined with regimen and local measures, must depend upon the acumen of the physician, and upon the appropriate use of each or of all in particular cases and circumstances. But in most cases the patient should recline on a cool hair couch, should sleep, if married, apart from her husband, on a hair mattress, and avoid very warm feather or down beds, all sources of sexual excitement, and whatever appears to aggravate her complaints. She should preserve an open state of the bowels by means of cooling aperients, or of these conjoined with tonics. The bicarbonates of the fixed alkalies may be taken with the nitrate of potash in bitter infusions, or the liquor ammoniæ acetatis with nitrate of potash, in similar vehicles. The terebinthinate embrocation already advised (§ 101) may be employed externally, and a cooling, and yet tonic or restorative, regimen and diet adopted, avoiding much animal food, and all heating and stimulating beverages, as well as coffee and strong tea. In a severe and tedious case, for which I was consulted by Mr. BARNWELL, the following pills proved of very great service:

No. 366. R Camphoræ rasæ, ℥j.; Potassæ Nitratis, ʒj.; Sodæ Sub-carb. exsic., ʒss.; Extr. Hyoscyami, ℥ij.; Syrupi papaveris, q. s. Misce. Fiat massa æqualis, quam divide in Pilulas xxx., quarum binas, ter in die capiat.

After these were taken for some time, they were replaced by the infusion of calumba, bicarbonate of soda, tincture of calumba, and tincture of hyoscyamus.

108. In the above manner, the *second indication* of cure may be initiated, and may thus advance to a more tonic and restorative or nutritious treatment, so as to restore the constitutional energies, and thereby the healthy state and functions of the uterus. This end can be attained only by medicinal and regiminal means, both of which, however, should be commenced with caution. In a few instances I have prescribed, with marked benefit, the *cod-liver oil*, on the surface of a tonic infusion, with one of the mineral acids, as the compound infusion of orange peel with sulphuric acid; or the compound infusion of roses, or the infusion of cinchona with hydrochloric ether or hydrochloric acid, or with both. In other cases, the tonic or bitter infusions or decoctions may be ordered with the alkaline carbonates, nitrate of potash, and tincture either of henbane or of some other anodyne. In cases which have been of long

duration, or have been caused by self-pollutions, or which are characterized by shattered health, by pallor of the countenance, cold extremities, and more or less anæmia, the milder preparations of iron, as the tincture of the muriate or of the acetate of iron, may be prescribed with the preparations of calumba or quassia. Dr. DAVIES states that he has given, in these cases, the phosphate of iron with much benefit. In some cases, especially where there is hypertrophy of the cervix uteri, the iodide of iron may be tried in the sirup of sarzæ; or the iodide of potash may be taken with either the bicarbonate of potash or the solution of potash in a tonic infusion, &c.

109. The *mineral waters*, natural or artificial, may likewise be resorted to, according to the peculiarities of the case. The Bath and Tunbridge waters, the Harrogate waters, the waters of Seltzer, Geilnau, of Ems, of Vichy, of Pymont, &c., have been severally recommended, and found of some service. The *regimen and diet* of the patient are of much importance. If married, she should sleep apart from her husband; and whether married or unmarried, she ought to avoid all causes of excitement and irritation. She should enjoy the advantages of a cool and pure air. The *diet* ought, while febrile and inflammatory symptoms are present, to be light, cooling, and chiefly farinaceous; and animal food should be given in very small quantity, until convalescence is advanced, when it may be taken more liberally. The beverages may consist of toast-water, barley-water, or of lemonade, or of the imperial drink. Afterward, when recovery is far advancing, the Rhénish wines, or claret, or claret and water, &c., may be allowed. In most cases, coffee and tea are inappropriate. Cocoa, or cocoa-nibs, prepared in a simple manner, and dry-toast with little butter, should be preferred. Patients who have caused this complaint by self-pollutions have generally great appetites; and their indulgences in food and in their unnatural vice tend to perpetuate the disease, and to frustrate the treatment. For them, the diet should chiefly consist in a large proportion of vegetable and farinaceous substances, whereby the stomach may be filled, with as little excitement of the circulation as possible. The mind should always be occupied by useful pursuits, and, as much as may be, by agreeable employments.

110. *E. Treatment of Inflammation of the Cervix Uteri in the unmarried, during and after Pregnancy, and in advanced Life.*—A well-informed practitioner may apply what has been already adduced to these circumstances of life, but with due care and precaution. In *unmarried females*, the great difficulty of treatment is in the local or instrumental part; but a recourse to it will depend much upon the severity and other peculiarities of the case, and upon the results of constitutional treatment, which should be previously employed, the causes of the disease having been ascertained, and removed as far as possible. "The existence of *pregnancy*," Dr. H. BENNET states, "so far from being an obstacle to the local treatment of inflammatory and ulcerative disease of the uterine neck, is a strong reason why it should be adopted and carried out without delay, unless the patient have reached the latter period of her pregnancy. If so, as the child is viable, and it is rather difficult to bring the cervix fully into view, it is as well, unless the symptoms be urgent, merely to resort to astringent injections, and to reserve all instru-

mental treatment until after the confinement." In the early or first six months, the local treatment, Dr. B. states, must consist in astringent injections, and cauterization with the nitrate of silver or the acid nitrate of mercury, the potassa cum calce being much too powerful in these cases. If ulcerative disease of the cervix exist after an *abortion or confinement*, he never interferes until four or five weeks have elapsed, and he then cauterizes the diseased surface with the nitrate of silver. If blood be poured out from the ulcerated surface, the cauterization invariably stops it; and the case then falls into the general category. But it should be recollected that, during lactation, the mucous surface of the cervix and vagina presents a vivid red or congested hue, from sympathy with the mammae and nipples; hence this condition should not be mistaken for inflammation, and ought not to be interfered with by treatment. The disease of the cervix in females *past the menstruating age* is generally intractable, and requires the most powerful caustics, but having been removed, the cure is permanent.

111. ii. *TREATMENT OF ACUTE INFLAMMATION OF THE INTERNAL SURFACE AND BODY OF THE UTERUS.*—Although the treatment of *endo-metritis*, by local means, is supposed, especially by some French writers, to be appropriate to this state and seat of the disease, yet such means, however cautiously resorted to, cannot fail of being more or less dangerous. As this form of metritis frequently commences in the cervix or its cavity, extending to the cavity, and to some extent, in most instances, to the substance or body of the organ, and in some cases also to the broad ligaments, these circumstances should always be considered, and the treatment should be prompt and decided. If the patient be young, or strong, or plethoric, especially if the disease has followed the suppression of the catamenia, or of other evacuation or excretion, blood should be taken from the arm, or from a vein in the feet immersed in warm water, and cooling diaphoretics and aperients exhibited. The warm or tepid bath, or hip-bath, may follow the depletion; and, if the pain be severe, camphor, nitrate of potash, and extract of henbane, or extract of belladonna, or a minute dose of aconite, may be prescribed every four or five hours, or after longer intervals, if the belladonna or aconite be given. In the cases just described, local depletions—by leeches applied over the ovarian regions, or below the groins, or by cupping on the loins or sacrum—may be directed after the *blood-letting*, especially if this latter has not produced the desired amount of benefit; indeed, in most cases the local depletions will also be required. In milder cases, and in less robust or plethoric females, the local depletions, when resorted to with decision, will generally be sufficient, especially when the internal or general treatment is judicious. Their repetition may, in some cases, be required, but this, as well as the quantity of blood which should be taken, should depend upon the severity and other features of the case. After the local depletions a tepid bath, and subsequently the terebinthinated epithems and embrocations already advised, may be placed over the hypogastric region, the flannel on which the embrocation is sprinkled having been either warmed or wrung out of hot water.

112. These measures having been employed, time should be allowed for their operation, and for the subsidence of the disease. This latter ob-

ject will, however, be promoted by rest in the horizontal posture; by the avoidance of sexual excitement; by recourse to cooling diaphoretic medicines, especially the liquor ammoniæ acetatis, with small doses of the vinum or liquor antimonii tartarizati, and some anodyne or narcotic. The only aperients allowed should be cooling, and such as may not irritate the rectum: as the citrate or carbonate of magnesia; the phosphate of soda; the acetate or tartrate of potash, prescribed in emollient vehicles, or with either of the preparations of senna or rhubarb. Calomel, or calomel with opium, should not be given in metritis, as it is apt to aggravate the complaint by irritating the rectum; and medicines containing aloes should also be avoided.

113. The *regimen* and *diet* of the patient should be strictly antiphlogistic, and the beverages allowed ought to be demulcent, emollient, and slightly alkaline. As convalescence advances, the alkaline mineral waters of Vichy or Ems may be allowed. When the disease is neglected, or improperly treated, it may extend to the broad ligaments and ovaria, as shown above (§ 72, *et seq.*), or it may lapse into a chronic state; which state, however, may be primary, although it is much more frequently a consequence of chronic inflammation of the cervix, or of the cavity of this part, or of the body of the organ, and is most frequently partial or limited in its seat, as shown above (§ 64).

114. iii. THE TREATMENT OF CHRONIC METRITIS.—Chronic metritis, often commencing in the cervix, is also frequently kept up by the inflammation of this part and its consequences. In most cases, therefore, the disease of the cervix should be first and chiefly attacked, by the means already advised for the several morbid conditions of this part (§ 102, *et seq.*). The chief local means are, rest in the horizontal posture, emollient or astringent vaginal injections, the occasional application of leeches to the cervix, before or after menstruation, according to the period at which they appear most serviceable, and a recourse to anodynes when the sufferings of the patient are severe. These latter, or the narcotics already mentioned (§ 93); a recourse to belladonna, both locally and internally, or to chloroform, or to the hydrochloric ether, or hydrocyanic acid, &c.; the introduction of opiate or other anodyne injections or suppositories into the rectum or vagina; and the external embrocations and epithems already advised (§ 101), are the chief means by which we may hope to remedy this state of disease. In obstinate and protracted cases, M. GENDRIN and Dr. H. BENNET have had recourse to an issue formed above the pubes, keeping it open for some months. In a severe and prolonged case, which I attended with Mr. FLOCKTON, many years before the appearance of this recommendation, I directed an issue to be made below both groins, with the most complete success.

115. The enlargement, partial or general, of the cervix and body of the uterus, in protracted chronic metritis, suggests not merely the local measures noticed above for reducing this enlargement, and the other evils which usually attend it, but also such other general or constitutional means as are sometimes found of service in removing other states of enlargement, morbid deposition or growth. These means may not be of much avail in the disease now under consideration; but the most important of them may be so

employed and combined as to very considerably improve the general health, which is usually injured by the local malady, and to alleviate the sufferings of the patient. These means are, the bichloride of mercury, the preparations of iodine, the iodide of arsenic and mercury, the fixed alkalies and their salts, and the preparations of sarza, severally but separately conjoined with tonics, anodynes, or narcotics, &c. On these principal medicines I proceed to offer a few remarks, in respect to the treatment of chronic metritis and its complications, especially when characterized by enlargement of any part of the uterus.

116. The *bichloride of mercury* is beneficial or injurious, according to the manner of prescribing it. It may be of service even when the constitution has been very remarkably injured by this protracted malady. But it should in most instances, and in these especially, be prescribed either in the fluid extract of sarza, or in the compound tincture of cinchona, or in the decoction or in mixtures, consisting chiefly of all these, with or without some narcotic, as the tincture of conium, or of henbane, &c., or with a few drops of the tincture of opium, or with the compound tincture of camphor, if the medicine should have too relaxing an effect on the bowels. This substance, thus taken, in doses varying from the sixteenth to the eighth of a grain, has a very salutary tonic and alterative effect, even although the hypertrophy of the uterus may not be much, or even at all, reduced by it.

117. The preparations of *iodine* are of service only when given in small doses, and continued for a considerable time. The *iodide of potassium* I have, in these cases, prescribed in doses of one to two grains, thrice daily, with the bicarbonate of potash, or liquor potassæ, or BRANDISH'S alkaline solution, in a tonic infusion or decoction, or as I have prescribed the bichloride of mercury (§ 116). The *iodide of mercury and arsenic* is sometimes of service when extemporaneously prescribed in the compound fluid of sarsaparilla, or in any better infusion. The *iodide of iron* may also be given in the form of pill (see *Form.* 535), or in the sirup of sarsaparilla, but in moderate doses, and in cases evincing more or less anæmia, and when there is reason to suspect that the disease has been caused or prolonged by self-pollutions. In these cases, also, the carbonates of the *fixed alkalies*, the tartrates, the nitrates, &c., are of service, when taken in tonic or bitter infusions, and conjoined with *anodynes or narcotics*. I have had reason to believe that the combination of the *bicarbonate of soda* with these, in doses sufficient to preserve the bowels in an open state, without offending the stomach, has been of more service in reducing hypertrophy of the uterus, whether partial or general, than any other means.

118. Dr. H. BENNET states that, when all ordinary therapeutic agents fail to remove chronic inflammation and induration of the uterus, he has established, as a counter-irritant, an artificial ulceration or issue in the neck of the uterus itself, with potassa fusa, or potassa cum calce, independently of any disease of that region, and with very great benefit to the patient.

119. As the chronically inflamed and enlarged uterus often falls back upon the rectum, thereby causing constipation and painful defæcation, especially when the fæces are more or less solid, care should be taken to preserve the bowels in an open state. The means which I have usually

preferred are electuaries, composed of the bi-tartrate of potash, the bi-borate of soda, and the confection of senna, sometimes with sulphur, and with any suitable sirup; which may be taken every night. They have a deobstruent effect upon the uterus, while they preserve a lax state of the bowels. In cases where emaciation or anæmia are prominent, in addition to nutrients, restoratives, or tonics, as circumstances have suggested, I have prescribed the cod-liver oil, and more recently this oil containing some of the preparations of iron, of iodine, or of mercury, &c.

120. iv. THE TREATMENT OF ENLARGED UTERUS hardly differs from that recommended for *chronic metritis* (§ 114, *et seq.*). Rest, attention to the secretions and excretions; cooling saline aperients and diaphoretics, local depletions, in moderate quantity, at intervals of about a fortnight; the preparations of iodine in small doses, with alkaline solutions or the bicarbonates; the bichloride of mercury in minute quantity, either alone or with the preparations of cinchona; the liquor potassæ with sarsaparilla; and more especially the avoidance of sexual excitement, and of all heating or stimulating beverages, and the recumbent posture, on a cool sofa, and on a hair mattress at night, are the means which will alone be of any service, if they be perseveringly adopted.

121. v. TREATMENT OF INFLAMMATION AND ABSCESS OF THE UTERINE APPENDAGES.—At an early stage the treatment of inflammation of the uterine appendages is the same as that advised for acute metritis (§ 111). But in order to prevent suppuration, which is very much more liable to occur in the former than in the latter, more prompt and more decidedly antiphlogistic measures are required, especially general and local blood-letting. If, however, these means fail in preventing the formation of *pus*, or in procuring the absorption of whatever may have already formed, the purulent collection will find its way to the exterior by the vagina, rectum, abdominal parietes, or bladder. In these circumstances we can only endeavour to control the symptoms, by means suitable for this purpose, to assist nature in throwing off the morbid formation, in the direction to which she points, to support the constitutional powers of the patient, in order that this end may be attained, and to palliate the more distressing symptoms which present themselves. The treatment advised for chronic metritis is suitable for this stage of the disease. If the abscess open into the urinary bladder, the means required will be suggested by the state of the urine. If this excretion continue acid, the carbonates of the alkalies, with demulcents, opiates, or other anodynes, will be most serviceable; and tonics, restoratives, the preparations of buchu, or pereira, &c., be also required. If the urine become ammoniacal, or even neutral, the mineral acids, with cinchona, quinine, or other tonics, opiates, &c., should be exhibited. If the abscess open in the rectum, or flexure of the colon, the consequent tenesmus, and other dysenteric symptoms, will subside after a short time, if, with restorative and anodyne medicines, amylaceous or mucilaginous injections, with opiates, be administered. The bursting of the abscess into the vagina terminates favourably if the constitutional powers be supported, and the unpleasant symptoms palliated, the vagina being occasionally washed by a lotion of tepid or of cold water. If the abscess point externally, tonics, with alkalies, and attention to

the excretions, are necessary; and as soon as fluctuation and redness of the tumid surface appear, an opening, made by the lancet, should not be delayed. Afterward, the powers of life should be duly supported; and the ingress of air into the cavity of the abscess carefully prevented, while the reaccumulations of matter should be prevented or moderated by gentle pressure; and whenever any collects, it should be discharged.

122. IV. INFLAMMATIONS OF THE UTERUS AND APPENDAGES OF A SPECIFIC NATURE.—Inflammation of the uterus may be caused by gonorrhœa or by syphilis—by gonorrhœa more frequently than is generally supposed, by syphilis very rarely.—i. I have seen several cases of GONORRHOEAL INFLAMMATION OF THE WOMB AND APPENDAGES, and in every case the disease was most severe; and whether extending to the os and cervix uteri from the vagina, or by possibility commencing in the former, owing to the direct contact of the morbid matter with that part, the inflammation had advanced along the canal of the cervix to the internal cavity of the uterus, and in three cases to the broad ligaments and ovaria—in one to both ovaria, and in another to the ovarium of the left side and pelvic peritoneum. Mr. Acton, in his excellent work on "*Diseases of the Urinary and Generative Organs in both Sexes*," has treated this subject in a chapter on "Blennorrhagia of the vulva, urethra, vagina, uterus, and ovary," but he views the disease as in all respects the same as inflammation of those parts, occurring independently of a specific contagion. That it is the same as respects the inflammatory condition—that it is an acute form of inflammation, there can be no doubt; but that it is more severe, more disposed to extend to the uterine cavity and appendages, than common inflammation, whether acute or chronic, commencing in the cervix uteri and produced by other causes, would appear from the cases I have treated. All these cases were of married women, the gonorrhœal infection having been communicated by their husbands, and in all the infection was most manifest, the patients not being previously subject to any leucorrhœal discharge, and was followed by most severe symptoms of inflammation of the womb, and by the extension of the inflammation still farther, as stated above. On this subject Mr. Acton remarks that, "a female suffering under uterine blennorrhagia may be seized with shivering and a feverish state of the system; vomiting may come on, together with pain referred to the iliac fossa, where more or less tension may be present (in no way resembling the superficial pain produced by peritonitis); but if the finger be carried up the *cul de sac* of the vagina, and the patient desired to turn upon the opposite side, pain of a most acute kind will be felt. The blennorrhagia may cease for the moment, one ovary may be attacked only, or both simultaneously, as in epididymitis; revulsion will explain the partial cessation of the discharge. Lastly, we believe that a great number of ovarian dropsies may result from a chronic inflammation of that organ, the consequence of such complications." (*Op. cit.*, p. 308.) I can fully confirm the correctness of this last remark by a recent case of ovarian dropsy, which occurred in the wife of a very eminent man, and was the ultimate lesion which followed gonorrhœa communicated by her husband. She was from the commencement, and is still, under my professional care.

123. i. SYPHILITIC ULCERATION OF THE CERVIX UTERI.—Both Dr. HENRY BENNET and Mr. ACROX agree in considering syphilitic ulceration of the cervix as a rare occurrence. The latter remarks that, in the vagina and os uteri, the circumstances favouring contagion do not often occur, for if the contagious pus of chancre reaches as far, it is generally deposited on a layer of mucus, which protects the membrane beneath. He concludes that "ulcerations of the neck of the uterus are, in ninety-nine times out of a hundred, merely simple affections, the result of acute or chronic inflammation, very intractable in ordinary treatment, and will persist an almost indefinite time, unless we employ local applications." True syphilitic ulcers of the cervix uteri are described by Mr. ACROX as differing from all other ulcers of this part. "They are small, covered with a chamois leather secretion, which it is difficult to remove; their edges are distinct; they look as if a portion of mucous membrane had been punched out of the os uteri, and inoculation has shown that they were true chancres, situated on this unusual position." (*Op. cit.*, p. 292)

124. ii. *The treatment of these specific diseases of the uterus is not different from that advised for the affections above described.*—A. As respects gonorrhæal inflammation of the womb and its appendages, the means are the same as those advised for the more acute inflammations of these parts; the chief modifications consisting in a more prompt and decided use of these means, especially when the symptoms are very severe. In many cases, the inflammation of the vagina is so severe, and the swelling of both it and the vulva so great, as to prevent a recourse to many of the means already advised, especially at an early stage, injections of an emollient and anodyne kind being first prescribed, and sedatives, demulcents, refrigerants, and narcotics internally. In other respects, and as the disease continues or is prolonged, the remedies already recommended for inflammation of the uterus and its appendages, should be administered appropriately to the peculiarities and complications of individual cases.

125. B. *The treatment of syphilitic ulceration of the cervix consists in the use of the acid nitrate of mercury locally, as directed above (§ 104), and in the employment of the constitutional means indicated by the existing state of the case, and by the appearance of any signs of VENEREAL CACHEXIA (see that article)*

126 V. DISPLACEMENTS OF THE UTERUS.—The womb being suspended in a cavity more or less capacious, but liable to alterations in the extent of its capacity; its supports being not only yielding, but also admitting of considerable mobility; its manifest changes in size and position during pregnancy; and its movements during coition, and the venereal orgasm, are circumstances requiring consideration while endeavouring to describe and explain displacements of the uterus, as well as to remedy these evils. The causes of these disorders are often manifest, but in some cases they can only be inferred from insufficiently conclusive evidence.\* It is not to be disputed

that an enlargement of the organ will favour its descent; that muscular efforts, especially lifting heavy weights, will have the same effect, even independently of enlargement, and particularly when the vagina and ligaments are relaxed by child-bearing, leucorrhœa, &c.; and that partial or general enlargement, the pressure of loaded adjoining viscera, too severe or prolonged exertion, especially during the menstrual period, falls on the back, hips, concussions of the trunk of the body, &c., will occasion either that or other forms of displacement.

127. It should not be overlooked that, in the great majority of instances of displacement of the womb, other lesions of the organ, either inflammatory or structural, are associated with the displacement. This circumstance is of no mean importance both in recognising the cause, conditions, and relations of displacement, and in regulating the treatment and regimen of the patient.

128. i. DESCENT OR PROLAPSE OF THE WOMB IS the most common form of displacement, and proceeds from increased weight of the organ, or from impaired tone of its supports.—A. Dr. WEST has considered this lesion with reference to its grades, and divided it into the *first*, *second*, and *third* degrees of prolapse. "In the *first* degree the organ is merely lower than natural, but still preserves its proper direction, its axis corresponding with that of the pelvic brim, and this, even though it should be so low that its cervix rests upon the floor of the vagina. In prolapsus of the *second* degree, the uterus is situated with its fundus directed backward, its orifice forward, so that its long axis corresponds with the axis of the pelvic outlet. In prolapse of the *third* degree, or, as it is often termed, *procedentia* of the uterus, the organ lies more or less completely externally, hanging down beyond the vulva, though it generally admits of being replaced within the vagina, if not of being altogether restored to its natural position." It is obvious that a due recognition of the circumstances, both physical and pathological, favouring and causing this displacement, is of the greatest importance in preventing and removing the different grades and complications of it observed in practice. The womb is not merely suspended by the duplicatures of the peritoneum within which it is contained, but it is also poised upon the vagina, which, in the healthy virgin state especially, furnishes it very considerable support. The curved direction of the vagina, the connexion of the organ, appendages, and vagina with the adjoining viscera, with the pelvic and perineal fasciæ, &c., also aid in supporting the uterus in its situation.

129. These combined supports, however, may prolapse." ("A Practical Treatise on Inflammatory Ulceration and Induration of the Neck of the Uterus." Lond., 8vo, p. 212, 1845.) When we consider, however, that the weight of a non-gravid womb seldom exceeds two ounces, and of that the vaginal cervix constitutes not more than one fifth part; and, moreover, that the gravid uterus at three or four months of gestation rarely descends, we may well doubt whether much can be justly attributed to this cause. Ninety per cent., at least, of these cases occur in females who have had children, and probably a still larger proportion, so that we must look to gestation and labour, and accidents connected with them, as the principal causes. Professor BEDFORD has very properly called attention to the fact, that both prolapsus and procedentia of the womb are often owing to mismanagement of the placenta, as pulling upon the cord before it is detached ("Clinical Lectures on the Diseases of Women and Children." N. Y., 8vo, 1855, p. 46, &c.), and some of the worst cases we have ever treated could be traced to this cause.]

\* Dr. J. H. BENNET, of London, was the first writer who attributed descent of the womb to an increase in its weight. "The uterus," he remarks, "is so slightly poised or suspended in the cavity of the pelvis, that the slightest modification in its volume gives rise to a change in its position. The inflammatory hypertrophy of the cervix increasing considerably the specific gravity of the inferior portion of the uterus, the entire organ descends,

severally be relaxed or overcome during the epochs of life following puberty. In the virgin and unmarried state, leucorrhœa, menorrhagia, anæmia, exhausting discharges, and frequent excitement of the venereal orgasm by masturbation, severally tend to relax the tone of the parts which support the womb in its natural position. During the sexual orgasm its mobility is manifested to the greatest natural extent, its descent often occurring in various degrees, without becoming greater than is consistent with the healthy function; but it is obvious that, when unnaturally produced, the healthy condition is at last exceeded, and that more or less displacement is apt to occur, especially as the same cause practised to excess tends remarkably to relax the tone of the parts upon which the healthy position of the organ depends. In the married state, as well as sometimes in the unmarried, although more remarkably and much more frequently in the former, enlargement and greater weight of the womb, and the stretching, relaxation, and other changes of the supporting parts consequent upon abortions, child-bearing, difficult labours, and puerperal diseases, very materially predispose to the descent and other displacements of this organ. If, in these circumstances, the erect posture be too early resumed after delivery or abortion, if falls or contusions of the trunk of the body be experienced, or if violent muscular efforts be made, as in lifting or carrying heavy weights, a greater or less descent, or hernia of the uterus is apt to take place. Aged and emaciated females, married or unmarried, are most frequently liable to this displacement, sometimes to its utmost extent, owing to the absorption of the adipose tissue adjoining the vagina and vulva, especially when the exciting causes just mentioned have occurred.

130. Descent of the uterus, even in its first and second degrees, is very commonly attended by some degree of retroversion; and this state is often, as well as the descent, increased by constipation of the bowels; the hardened fæces, in the efforts at defæcation, augmenting the extent of both states of displacement, by pressing upon the fundus of the uterus. Dr. West justly remarks that "the close connexion between the cervix uteri and the neck of the bladder is a temporary obstacle to the complete descent of the womb, while at the same time it favours the retroversion of the organ; but if at length this yields, the urine accumulating in the bladder distends its fundus and the vaginal anterior wall into a pouch which drags down the uterus in front just as the prolapse of the rectum drags it down behind; and the organ now soon comes to lie beyond the external parts; the ease being thus converted into one of procidentia uteri, or of prolapse in the third degree." (*Lect.*, p. 156.)

131. This displacement of the uterus is, in the course of time, followed by still farther changes. The neck of the womb, being the first part protruded, and the most exposed to irritation, becomes more and more hypertrophied, and often excoriated; the enlargement being both in length and thickness. The protrusion of this part of the organ is partly due to inordinate growth, its thickness being sometimes equal to, or even greater than that of the wrist. The lips of the os uteri become enlarged with the rest of the organ, and the transverse opening formed in women who have had children is converted into a wide opening situated deeply between projecting lips, whose

surface is irritated, excoriated, vividly red or granulated, and covered by an albuminous secretion. The prolapse beyond the vulva may continue only in a partial state for years, the fundus and a portion of the organ remaining within the pelvis, while the neck and the lower part are external. In this state, the organ may still be replaced without difficulty, especially when the prolapse has followed soon after delivery at the full period, the pelvic floor being sufficiently yielding in most instances. In the course of a variable duration of time, a partial descent is often followed by a complete protrusion of the organ, "the vagina becoming inverted, and forming the outer walls of a tumour, at the lower part of which the womb is situated. So long as the procidentia is incomplete, this tumour is somewhat pyriform in shape, its base being directed upward; but afterward, as it increases in size, it assumes an oval form, owing to more or less of the bladder being drawn down into it in front, and of the rectum also, in many cases, behind. Its bulk is also farther swelled, in numerous instances, by the small intestines sinking down into the sac, and thus adding to its size until it equals or exceeds that of the adult head."

132. In these cases, the uterus itself forms only a comparatively small portion of the large external tumour. The susceptibility of the organ, and the disposition to hypertrophy, are much diminished by constant and complete prolapsus from the pelvic cavity. "The bulk of the tumour, and the difficulty of its replacement, depend chiefly upon two causes. Of these, the one consists in the enormous hypertrophy which the vaginal walls undergo. Not only does their mucous membrane lose its ordinary character and become covered by a layer of cuticle like that of the skin, to protect it from the various sources of irritation to which it now becomes exposed, but the walls themselves attain a thickness of as much as half an inch, and present a dense muscular structure. The other cause of the bulk of the tumour, and of the difficulty of replacing it, arises from the presence of the intestines in the sac, which seldom reside there long without inflammation of their peritoneal covering being set up; not of so acute a character, indeed, as to produce formidable symptoms, nor even as always to call for treatment, but matting their different coils to each other, and tying them firmly to the interior of the sac." This latter cause of difficulty in attempting to return a long procident uterus should not be overlooked, for, even though no intestines have descended into the external tumour itself, chronic peritoneal inflammation may agglutinate them to each other, or to the walls of the pelvic cavity, and thus oppose the replacement of the womb.

133. *B. The Symptoms of Prolapse of the Uterus.*—The symptoms may be severe in some cases, and hardly experienced in others. In the unmarried, and when occurring suddenly or rapidly, prolapse of the uterus is attended by much more severe or acute symptoms than when it occurs in married females after miscarriage or delivery, or when it takes place slowly. When it is caused in single females after prolonged dancing or riding on horseback, the symptoms are generally rapid and severe; and even in married females who have borne children, and have subjected themselves to these causes, the descent is usually rapid, and the symptoms are also severe, but the prolapse is generally greater than

in the single. The sensation most frequently experienced is that termed "bearing down," or of falling down of the pelvic viscera. This feeling is augmented by lifting weights, or by bodily exertion, and then it is often attended by a sharp pain. Defæcation is difficult and painful, and is followed by some degree of tenesmus. Pain in the direction of the vagina, when sitting down, especially on a hard seat, pain in the back and low in the sacrum, and a very frequent desire to pass water, are always experienced. Leucorrhœa is often complained of, and the catamenia are either profuse, prolonged, or too frequent. The digestive organs are soon after more or less disordered, the bowels are constipated, and the general health suffers; and as the prolapse becomes chronic or prolonged, the cervix and even the body of the uterus become hypertrophied.

134. External prolapse, or procidentia uteri, generally follows the internal prolapse, or that in which the uterus and cervix still remain within the external parts, and usually takes place gradually. It is favoured by emaciation or the absorption of the adipose substance in the vicinity of the vulva; and it occurs most frequently after a too early change of position after parturition or miscarriage, or too early exertion, or walking about, after these occurrences. In these circumstances especially, sudden, unusual, or great exertion, or straining at stool, or lifting weights, may occasion procidentia suddenly; and the symptoms may then be severe. As the cervix, the lower part, and the body of the organ, successively protrude—the former parts only occasionally at first—the pains, inconvenience, and distress increase, and ultimately the whole organ lies nearly always or constantly without the external parts. After the protrusion, the sensibilities of the uterus become blunted by the exposure, and the vaginal leucorrhœa subsides. But, as the procidentia increases, the relations of the uterus with the adjoining organs and parts are changed. The urinary bladder and urethra are more particularly implicated, occasioning dysuria, a frequent desire to empty the bladder, or incontinence of urine. The rectum is also affected so as to render defæcation difficult or painful; while the descent of the small intestines into the pelvic cavity, and the excoriations, thickening, irritation and ulcerations of the exposed parts, owing to exposure to the air, and to the dribbling of urine, and to other contingent occurrences, increase the sufferings of the patient. With the complete prolapsus, hypertrophy of the organ increases, more especially its cervix and the lips of the os tincæ, which, moreover, become ulcerated to a considerable extent, the cavity of the cervix being drawn apart, so as to become open or gaping, the ulcerations extending into it. In many cases of internal prolapse, pregnancy takes place; but this period is often one of considerable suffering. If the prolapse be slight, pregnancy generally cures it, as the uterus rises in the pelvis with the advance of gestation, especially if care be taken, and the patient remains in a recumbent position long after delivery. When the uterus is either *partly* or *altogether* external, impregnation rarely takes place. In the former case, the sufferings of the patient are greatly increased by impregnation; and miscarriage usually takes place, the organ being unable to rise into the pelvic and abdominal cavities. "In some few instances, however, pregnancy runs its course undisturbed, in

spite of a great degree of prolapsus; and cases are on record in which the uterus has descended farther and farther, until a great portion of it hung down between the thighs; but the development of the fœtus has, nevertheless, gone on in this unnatural position; and others still stranger, in which coitus has been practised immediately through the os uteri, and impregnation and undisturbed gestation have followed in spite of the existence of irreducible procidentia." (WEST, *Lect.*, p. 172.)

135. *C. Treatment.*—The causes which tend to oppose the return of any long-existing procidentia of the uterus have been explained above (§ 132); and the same causes, although operating in a less degree in simple or internal prolapsus, often prevent the complete restoration of the womb to its normal position. The first object, in respect of treatment is, to ascertain the causes of prolapse, and the circumstances connected with its occurrence and progress; for the means of cure or of palliation must be directed accordingly. Carefully avoiding the causes of prolapse (§ 126, *et seq.*), the patient should strictly observe rest and the recumbent posture; preserve a gently open state of the bowels, and have recourse to astringent injections, and the cold hip-bath. When the womb is much enlarged, as well as prolapsed, the measures advised above for the enlargement (§ 115–120) should be adapted to the peculiarities of the case. It should be recollected that there is always a tendency to a return of the descent, even when the womb has regained its proper position, upon the recurrence of the menstrual period. If, therefore, due care and proper precautions be not taken on the accession and during the course of this period, the descent may return, and each return will be attended by an aggravation not only of the extent of the prolapse, but also of the enlargement of the organ, and of the profuse menstruation which generally attends it, especially if the patient be allowed to remain in an erect or sitting posture.

136. As respects a recourse to mechanical supports in order to preserve the uterus in situ, as well as regards a selection of those supports, I must refer the reader to directions contained in Dr. West's very able and instructive lectures, and be contented with a reference to the more general principles and directions he has there adduced: 1st. In cases of slight descent of the uterus, resulting from a general loss of tone in the parts, or from some temporary or accidental cause, as excessive fatigue, over-exertion; 2d. In cases where the descent of the womb is still comparatively recent, and is due to the persistence of puerperal hypertrophy, owing to imperfect involution of the organ (§ 69) after abortion or labour; 3d. In cases where uterine disease, of whatever kind, was the occasion of displacement of the organ, such disease being still in a stage requiring treatment. In these several circumstances, mechanical support of the uterus is not necessary or suitable. On the other hand, mechanical means of some kind or other are required, 1st. In all cases of external prolapse or procidentia; 2d. In cases of long-standing prolapse of the second degree, associated with much relaxation of the vagina, and consequent weakening of the uterine supports; 3d. In all cases of extensive laceration of the perineum, and for a similar reason in cases of prolapsus in the aged; 4th. In cases of less degrees of prolapse attended by extreme suffer-

the uterus which consist of *versions* and *flexions*, or, strictly speaking, of *deviations of the body and neck of the organ* from their normal position, have only recently received due attention; and, although descent of the womb, in its several degrees, has been duly considered, owing to the prominent manner in which it is brought before those who have professed the study of the extensive class of female diseases, yet other deviations of the womb from its natural position have been, until lately, but imperfectly investigated by them, in the married and child-bearing states, and entirely neglected in unmarried females. This neglect has in great measure originated in imperfect knowledge or entire ignorance, 1st. Of the probability of the displacement being congenital; and, 2d. Of certain of the causes of these deviations, especially those causes which more frequently occur in unmarried than in married females, and to which I have sufficiently adverted already (see § 10, 22).

140. A Dr. W. HUNTER first directed attention to *retroversion* of the uterus as sometimes taking place in the early months of pregnancy; but it was not recognised as occurring in the unimpregnated womb until cases of it in this state were published by Professor OSIANDER in 1808, and Professors SCHWEIGHAUSER, in 1817, and SCHMITT, in 1820, farther illustrated the history and symptoms of this displacement. More recently, Professor SIMPSON, of Edinburgh, and M. VELPEAU, have fully investigated the nature and signs of the several deviations of the unimpregnated uterus from the normal state. Not only may the fundus of the womb fall backward into the hollow of the sacrum or forward against the symphysis pubis, but it may also incline towards either side. Its body may, moreover, be bent upon the cervix, forming a new class of deviations, called *flexions*; and Dr. WEST states that there is reason for believing that *retroflexion* and *anteflexion* are of more frequent occurrence than the corresponding alterations in position of the whole of the organ, which are known as *retroversion* and *anteversion*. The tendency of the womb when at all enlarged, either in the early period of pregnancy, or by disease, is not only to sink below its natural position, but at the same time to fall back with its fundus towards the hollow of the sacrum; besides, enlargement of the organ, either from imperfect involution, or from disease, is generally most considerable at its posterior parietes, thereby causing a tendency to fall towards the heavier side. The distention of the bladder also, so frequently continued for a prolonged period, and a loaded and constipated state of the bowels, aid in producing this form of deviation, whether in the gravid or in the non-gravid uterus; while sudden efforts or violent exertions, falls, concussions of the trunk, will concur with these and other causes or circumstances, as with the catamenial period in the non-gravid, in producing this form of deviation, namely, *retroversion*. Previous delivery, miscarriages, difficult menstruation, congestion of the uterus, intemperate sexual indulgence, and increased determination of blood to the organ, will also predispose to, or even cause, this occurrence, as well as some other conditions hereafter to be noticed (§ 142, *et seq.*).

141. B. *Anteversion* of the non-impregnated uterus was, only a few years ago, considered to be a rare occurrence. I find in the notes of a

case which I saw, with Mr. HOYLAND, in 1843, that I remarked that one to have been only the fourth that I had seen, and that this case was most probably owing to adhesions of the fundus of the uterus, as the lady had been some considerable time previously the subject of pelvic peritonitis. Madame BOVIN had, however, many years previously pointed out attacks of circumscribed peritonitis as a not infrequent cause of abortion. Without such adhesions it is difficult to account for the occurrence of anteversion, owing to the relative position of parts; and there is much reason for inferring, with Dr. WEST, that many of the cases believed to be those of *anteversion* were actually cases of *anteflexion*, the fundus of the organ having been bent forward on its cervix. But even in this case the explanation of its occurrence is not easy. In married females, however, some allowance should be made for the mechanical effects of sexual intercourse in connexion with the venereal orgasm in the female.

142. C. As respects the deviations usually termed *version* and *flexion*, Dr. WEST remarks "that in the greater number of cases of alleged version of the womb, either forward or backward, the organ is really flexed or bent upon itself; and farther, that not unfrequently the two conditions coexist, the whole womb being thrown more forward or more backward than natural, while in addition the body of the organ is bent upon its cervix." As far as the symptoms are concerned to which they give rise, these varieties of deviation present but little difference.

143. As to the point of *flexion of the uterus*, whether backward or forward, Dr. WEST agrees with Professor VIRCHOW, of Berlin, in considering it to be the junction between the body and neck of the womb, or, in other words, the spot corresponding to the internal os uteri; and that the flexion is owing to the anatomical fact that, while the neck of the womb is firmly connected with the posterior and lower part of the bladder, its body is perfectly moveable. As to the comparative frequency of the two forms of deviation, Dr. WEST states that his notes furnish the particulars of twenty-six cases of retroversion and retroflexion, and of nine of anteversion and anteflexion. M. VALLEIX, however, gives thirty-five deviations of the uterus forward, and thirty-three backward; and Dr. MAYER, of Berlin, sixty-three cases of the former, and sixty-four of the latter. The frequency of adhesions, and of other indications of previous inflammation, as a cause of deviations of the uterus, is shown by the statement of Dr. WEST, that he met with these lesions of the womb, its appendages, and the vicinity, in twenty-two out of sixty-six cases, in which he examined the uteri of women who had died of some other than uterine disease.

144. Protracted flexion of the uterus may be expected to be followed by farther lesions. These are narrowing of its cavity, at the point of flexion especially, and atrophy of the parietes of the womb on the side towards which the flexion occurs, thereby rendering it permanent.

145. The cervix is very generally more or less diseased in all the forms of deviation of the uterus, presenting the several states of lesion described above as being seated in the cervix externally and internally—these being chiefly indicative of inflammatory irritation or action, granulations, excoriations, ulcerations, enlargement of the cervix,

the uterus which consist of *versions* and *flexions*, or, strictly speaking, of *deviations of the body and neck of the organ* from their normal position, have only recently received due attention; and, although descent of the womb, in its several degrees, has been duly considered, owing to the prominent manner in which it is brought before those who have professed the study of the extensive class of female diseases, yet other deviations of the womb from its natural position have been, until lately, but imperfectly investigated by them, in the married and child-bearing states, and entirely neglected in unmarried females. This neglect has in great measure originated in imperfect knowledge or entire ignorance, 1st. Of the probability of the displacement being congenital; and, 2d. Of certain of the causes of these deviations, especially those causes which more frequently occur in unmarried than in married females, and to which I have sufficiently adverted already (see § 10, 22).

140. A. Dr. W. HUNTER first directed attention to *retroversion* of the uterus as sometimes taking place in the early months of pregnancy; but it was not recognised as occurring in the unimpregnated womb until cases of it in this state were published by Professor OSIANDER in 1808, and Professors SCHWEIGHAUSER, in 1817, and SCHMITT, in 1820, farther illustrated the history and symptoms of this displacement. More recently, Professor SIMPSON, of Edinburgh, and M. VELPEAU, have fully investigated the nature and signs of the several deviations of the unimpregnated uterus from the normal state. Not only may the fundus of the womb fall backward into the hollow of the sacrum or forward against the symphysis pubis, but it may also incline towards either side. Its body may, moreover, be bent upon the cervix, forming a new class of deviations, called *flexions*; and Dr. WEST states that there is reason for believing that *retroflexion* and *anteflexion* are of more frequent occurrence than the corresponding alterations in position of the whole of the organ, which are known as *retroversion* and *anteversion*. The tendency of the womb when at all enlarged, either in the early period of pregnancy, or by disease, is not only to sink below its natural position, but at the same time to fall back with its fundus towards the hollow of the sacrum; besides, enlargement of the organ, either from imperfect involution, or from disease, is generally most considerable at its posterior parietes, thereby causing a tendency to fall towards the heavier side. The distention of the bladder also, so frequently continued for a prolonged period, and a loaded and constipated state of the bowels, aid in producing this form of deviation, whether in the gravid or in the non-gravid uterus; while sudden efforts or violent exertions, falls, concussions of the trunk, will concur with these and other causes or circumstances, as with the catamenial period in the non-gravid, in producing this form of deviation, namely, *retroversion*. Previous delivery, miscarriages, difficult menstruation, congestion of the uterus, intemperate sexual indulgence, and increased determination of blood to the organ, will also predispose to, or even cause, this occurrence, as well as some other conditions hereafter to be noticed (§ 142, *et seq.*).

141. B. *Anteversion* of the non-impregnated uterus was, only a few years ago, considered to be a rare occurrence. I find in the notes of a

case which I saw, with Mr. HOYLAND, in 1843, that I remarked that one to have been only the fourth that I had seen, and that this case was most probably owing to adhesions of the fundus of the uterus, as the lady had been some considerable time previously the subject of pelvic peritonitis. Madame BOVIN had, however, many years previously pointed out attacks of circumscribed peritonitis as a not infrequent cause of abortion. Without such adhesions it is difficult to account for the occurrence of anteversion, owing to the relative position of parts; and there is much reason for inferring, with Dr. WEST, that many of the cases believed to be those of *anteversion* were actually cases of *anteflexion*, the fundus of the organ having been bent forward on its cervix. But even in this case the explanation of its occurrence is not easy. In married females, however, some allowance should be made for the mechanical effects of sexual intercourse in connexion with the venereal orgasm in the female.

142. C. As respects the deviations usually termed *version* and *flexion*, Dr. WEST remarks "that in the greater number of cases of alleged version of the womb, either forward or backward, the organ is really flexed or bent upon itself; and farther, that not unfrequently the two conditions coexist, the whole womb being thrown more forward or more backward than natural, while in addition the body of the organ is bent upon its cervix." As far as the symptoms are concerned to which they give rise, these varieties of deviation present but little difference.

143. As to the point of *flexion of the uterus*, whether backward or forward, Dr. WEST agrees with Professor VIRCHOW, of Berlin, in considering it to be the junction between the body and neck of the womb, or, in other words, the spot corresponding to the internal os uteri; and that the flexion is owing to the anatomical fact that, while the neck of the womb is firmly connected with the posterior and lower part of the bladder, its body is perfectly moveable. As to the comparative frequency of the two forms of deviation, Dr. WEST states that his notes furnish the particulars of twenty-six cases of retroversion and retroflexion, and of nine of anteversion and anteflexion. M. VALLEIX, however, gives thirty-five deviations of the uterus forward, and thirty-three backward; and Dr. MAYER, of Berlin, sixty-three cases of the former, and sixty-four of the latter. The frequency of adhesions, and of other indications of previous inflammation, as a cause of deviations of the uterus, is shown by the statement of Dr. WEST, that he met with these lesions of the womb, its appendages, and the vicinity, in twenty-two out of sixty-six cases, in which he examined the uteri of women who had died of some other than uterine disease.

144. Protracted flexion of the uterus may be expected to be followed by farther lesions. These are narrowing of its cavity, at the point of flexion especially, and atrophy of the parietes of the womb on the side towards which the flexion occurs, thereby rendering it permanent.

145. The cervix is very generally more or less diseased in all the forms of deviation of the uterus, presenting the several states of lesion described above as being seated in the cervix externally and internally—these being chiefly indicative of inflammatory irritation or action, granulations, excoriations, ulcerations, enlargement of the cervix,

and an open or gaping state of the os and cervical cavity, enlargement of the posterior lip of the cervix, &c. (see § 27, *et seq.*); these severally, or two or more of them jointly, being very frequent complications of deviations of the uterus from the normal state. That these lesions of the cervix are not always consequences of the deviations, my experience induces me to believe, and to infer that Dr. H. BENNET more correctly attributes the deviations to pre-existing disease of the cervix. It appears to me that those alterations of sensibility of the cervix associated with more or less irritation or chronic inflammatory action, and with the several consequences of sexual excitement, leucorrhœal discharges, disordered menstruation, and their numerous and ever-varying sympathetic affections, are more likely to give rise to deviations of the position of the uterus, and not only to the deviations already noticed, but also to others, consisting of obliquity of position, or to lateral deviations (which I believe to be the most frequent of any, and to be generally of temporary duration), when unconnected with disease of the ovaria and the broad ligaments, than that these deviations of the womb from its natural position should occasion disease of the cervix. It may be readily allowed that any pre-existing disease in this part may be aggravated by lesions of position; but that the former is a consequence of the latter, requires farther proof; and the positive evidence furnished of a different succession of lesions would require to be previously disproved.

146. *D. The symptoms of deviations of the uterus* have been subjects of contention even with those who have taken female diseases under their special protection. How, therefore, shall those who get only occasional glimpses of uterine diseases decide, when so very opposite views are entertained by the professors of this specialty? The former are, however, the judges in the cause; the latter are the partisans or advocates of their respective doctrines. Thus it is stated, by a very recent and able writer on these diseases, that "the symptoms are by some described as being both numerous and characteristic, and the appropriate treatment is by them alleged to be both simple, safe, and successful, while others deny that the mal-positions, taken by themselves, produce any symptoms, and assert that the proposed treatment, while attended by very considerable risk, is wholly inadequate to the removal of the evil which it is intended to cure. Each of these opinions, too, is maintained by men equal in the eminence of their position, in their practical experience, and in their good faith." (*Op. cit.*, p. 206.) This statement is borne out by the discussion on this subject reported in the "*Bulletin de l'Académie de Médecine*" for 1853-4 (vol. xix., p. 778-976), and is there fully and remarkably illustrated.

147. It is very obvious to the student of human nature, that, however well-informed individuals may be in their especial department, and however eminent in popular estimation, as long as occurrences, morbid actions, and their consequences, vary so as to give rise to modified or different signs, phenomena, or symptoms, and to develop modified or altered features or aspects, so long will the observers of these see and believe certain of them in preference to, or to the neglect of, the rest, and thus form one-sided views, which the very majesty of their position, in either professional or popular opinion, or both, will not admit of being impugned, and for which they will con-

tend with biased judgments, even in opposition to the most obvious truths. Now, as one of the professed judges in such matters, and having no preconceived opinions as regards them, I venture to state that the symptoms vary, in severity and number, with the causes—predisposing and exciting—with the sensibility and irritability of the sexual organs themselves, and of the constitution, with the existing deviation and its extent, with its several associations with disease of the cervix and its consequences, with the states of the natural and morbid uterine discharges, and with the several complications which deviations of the uterus present with the adjoining viscera. Hence it may be inferred that the slighter deviations which have taken place slowly or gradually in females evincing but little susceptibility or irritability, and which are not associated with marked disease of any part of the uterus, or of structures connected with it, may not occasion any disorder calculated to excite anxiety in the patient, or to require medical advice, and yet may exist for a long period, or may disappear altogether, from the efforts of nature or from changes in the female economy or in the constitution. But deviations of the uterus to a considerable extent, especially when occurring suddenly from well-recognised causes, and when associated with other uterine lesions, or with diseases of adjoining parts—and even when existing simply in susceptible, sensitive, or irritable females, married or unmarried, more especially in the latter when masturbation is suspected—then will very generally occasion symptoms which, if they do not prove, should at least induce the physician to ascertain its existence or non-existence by an examination. That the symptoms are often, however, more or less equivocal, or that they may frequently accompany other lesions of the womb, must be admitted, but a vaginal examination readily solves the difficulty, and evinces the true nature of the complaint. The symptoms usually present in uterine displacements or deviations are, excessive, painful, or difficult menstruation, leucorrhœal discharge, pain in the pelvis generally, and most severe in that part of the pelvis towards which the fundus uteri is turned or flexed, pain and difficulty in defæcation and micturition, constipation, frequent calls to pass urine, or sometimes retention of it, and sterility. According to the temperament and habit of body of the patient, various sympathetic disorders may be induced by uterine deviations, chiefly affections of the digestive organs, as nausea or retchings on the accession of the catamenia, hysterical symptoms, pain under or in the mammæ or in the spine, neuralgic pains in the limbs, &c.

[The above remarks of our author explain very satisfactorily the differences of opinion on this question between Dr. BENNET on the one hand, and Drs. TYLER SMITH, WEST, and R. LEE on the other. Because we meet with some cases in which inflammatory lesions of the neck of the uterus, including ulceration, exist, without creating constitutional disturbance or any particular suffering, it by no means follows that it is so in all cases. In some women, as Dr. BENNET has remarked, the organic sensibility of the womb and its sympathetic connexion with the rest of the economy are so slight, that severe uterine disease, inflammatory or other, may exist for months or years, as in other organs, without producing much local discomfort or much general disturbance; but then these must be regarded as

exceptional cases. It would be wrong to infer from these that inflammatory lesions are of no pathological importance. The same remark will apply to uterine displacements, and indeed all affections of the uterine organs, and it is in accordance with what we observe in all other parts of the body. On one point we must, however, express a doubt, and that is, whether the slight increase of weight attending hypertrophy of the neck, or even body of the womb, is the principal cause of prolapsus, or any other displacement. It may co-operate with other causes, possibly, but in itself alone it can have no important influence.]

148. As respects this disputed question, Dr. West justly remarks that, although cases prove, on the one hand, that flexions of the womb do not of necessity give rise to any distress, and, on the other, that the removal of a flexion of the organ may not be followed by relief of the patient's sufferings, the fact still remains that displacement of the womb is in very many instances attended by various uterine ailments not experienced before its occurrence. Here, however, the question suggests itself, Are the sufferings of the patient due simply to the displacement, or to the morbid condition with which the displacement is associated, or to the two causes conjoined? Dr. West answers this question by stating that "there are circumstances which appear to favour the opinion that, in the majority of instances, the symptoms are due not to displacement alone, but to displacement accompanied by some other morbid state of the womb." This opinion is confirmatory of that previously given by Dr. H. BENNET, that the deviation is nearly always a consequence of chronic inflammation of the cervix, is associated with the cervical disease to which the sufferings of the patient are mainly due, unless in extreme cases of displacement. For some remarks on the diagnosis of versions and flexions of the uterus, and on the use of Dr. SIMPSON'S uterine sound for this purpose, I must refer the reader to Dr. West's lectures, and to the other recent works on uterine disease. There can, however, be but little difficulty in the diagnosis between such deviations and tumours in the uterus, for which they can hardly be mistaken.

149. *E. The treatment of deviations of the uterus* has been a matter of dispute among modern authorities on uterine diseases. Certain of these contend that the lesions of the uterus to which the deviations are due, and to which the symptoms are chiefly owing, should be made the objects of treatment, while others attempt to restore the uterus to its right position, and to maintain it there by mechanical contrivances. SCHWEIGHAUSER, SCHMITT, OLDHAM, and others, have supported the former treatment, while Dr. SIMPSON, VELLEPEAU, KIWISCH, and VALLEIX have resorted to the latter. These contrivances have undergone various alterations in the hands of the several authorities who have had recourse to them. From what I have seen of cases in which they were employed,\* and from the opinions of M. DUBOIS

and Professor SCANZONI, as stated by Dr. WEST, I believe that, although they may be successful in some cases, under the care of able and careful practitioners, they are attended by no small risk, as respects the uterus, its appendages, and peritoneum, and that the return of the displacement is very frequent after the mechanical contrivance is removed. At a recent discussion in the Academy of Medicine at Paris, "M. DUBOIS stated that he had himself treated upward of twenty cases by means of the uterine supporter, which in some instances was worn for several months, but that the displacement reproduced itself within a very short time after the removal of the instrument; and that he had made a similar observation in the case of many patients who, having been thus treated by M. VALLEIX and Dr. SIMPSON, had been dismissed by those gentlemen as cured."\* Professor SCANZONI remarks that "the observation of fifty-six cases of flexion of the uterus during the past four years compels me to express my decided conviction that the mechanical treatment of this affection is either useless or positively mischievous." He concludes that, having quite discontinued the use of these mechanical contrivances, and contented himself with a recourse to cold vaginal injections, with the antiphlogistic treatment of any chronic uterine inflammation, and the application of caustic to any ulceration of the os uteri, and with the endeavour to remove the chlorotic symptoms which are seldom absent, he has been much better satisfied with the results of treatment than he was when he was seduced into the application of a variety of mechanical contrivances. (*Lect.*, &c., p. 225.)

150. It is obvious from the foregoing, as well as from my own limited experience, that attention to the improvement of the general health, to the removal of the local lesions of the uterus with which displacement is often associated, as they admit of removal by local and constitutional treatment, to alleviation of the more painful or distressing symptoms, and to the improvement of the secretions and excretions, are the true principles which should guide the physician in the management of these complaints. The means which are chiefly required are such as have already been recommended. If the catamenia be excessive, the sulphuric acid and sulphate of magnesia, or the supertartrate of potash, if the bowels be constipated; the sulphate of alum if this state do not exist, or the gallic acid, tannin, or the infusion of matico, may be prescribed internally, and conjoined with henbane, or with conium, or with the extract or tincture of belladonna, or of the Indian hemp, if pain be urgent. After the second or third day, if the discharge be excessive, cold enemata. The patients themselves were in favour of the treatment, but their general health appeared much impaired since they were my patients. I stated to the parents that I could not approve of the means employed for single females, that the contrivances could not be always applied, and that the complaint would return when they were relinquished. I therefore refused any farther interference in these cases.

[\* In 1849 I had an opportunity, through the politeness of Professor SIMPSON, of observing, for some time, his treatment of uterine affections, especially of deviations of the uterus, by means of his *stem-pessary*; and it is due to him to state that, although I examined several cases in which this instrument had been worn, some for a period of a year or longer, there was no instance in which the wearer complained of its causing irritation, pain, or serious inconvenience. These results, so different from what I had been led to expect, satisfied me that the dangers from the use of this instrument have been greatly exaggerated.]

\* In two of unmarried females who had previously consulted me for hysteria with leucorrhœa, the mechanical contrivance in question was resorted to by the physicians to whom they had subsequently confided their treatment. I was requested by the parents of these two young females to see them in consultation with the physicians then attending them, their parents having been dissatisfied with this treatment. The contrivances in use for them were shown me; their appliance and object were

mata may be administered twice daily; and in order to remove the anæmia and debility generally characterizing these cases, chalybeate preparations, variously combined, according to the circumstances of the case, should be given, and the diet and regimen strictly enforced.

[When we consider that the uterus has no fixed position in the pelvis, but is liable to be altered, both in its position and axis, by a variety of extraneous agencies—the state of the urinary bladder in front, the rectum behind, the intestine above, and the colon on either side, and consequently from a variety of morbid states incidental to these organs, it is liable to be deposed from its natural position, and to have its axis altered from its normal state—we shall be led to doubt the pathological importance and significance which are assigned by some to its displacement. Doubtless the same causes which give rise to abnormal states of the chylopoietic or abdominal viscera, simultaneously disturb the functions of the uterine and pelvic. We often discover uterine displacement where no uterine or constitutional disturbance is present; and we treat cases of retroversion, for example, and even prolapsus, successfully, by constitutional remedies, when there is considerable uterine and constitutional derangement. We are, therefore, disposed to believe that the uterine organs, in these cases, suffer in a secondary, rather than in a primary manner; and that, retroversion being a consequence of the more general derangement referred to, any treatment, to be successful, must be founded on the various antecedent conditions which gave rise to the uterine malady. If these remarks are founded in truth, then such mechanical remedies as the stem-pessary will be likely to do more harm than good; for the idea that the uterus is to maintain a fixed and undeviating position is opposed, as we have seen, to all correct physiological principles. We agree, then, with Dr. BENNET, that displacements of the uterus are constantly met with, but, except in extreme cases, they are in reality of secondary importance. They often exist in the healthy without being recognised or complained of; and they often remain after the removal of disease, without distress or inconvenience being experienced; while in those who suffer from uterine ailment, they generally coexist with decidedly inflammatory lesions. Their presence may generally be explained by these lesions; and they generally disappear by degrees, as the inflammatory lesions are cured and removed.]

Prof. HODGE, of the University of Pennsylvania, has introduced a pessary for uterine displacements, which is regarded by some as superior to all others, on the ground that it restores and maintains the vagina in its normal proportions. This instrument consists of two lateral bars, curved to correspond with the walls of the vagina, united at the top by a triangular bar. This instrument is said to maintain the vagina in its original shape, and thus keeps the uterus *in situ*, pressing away from rather than against the womb. It has the advantage of not being liable to derangement, and readily permits the natural functions of all the pelvic organs to be performed without obstruction, while it is worn without annoyance, and can be introduced and removed with great facility. It is also believed to be well calculated to replace the womb when displaced in any way, although it seems more particularly adapted to cases of retroversion. Here

the posterior wall of the vagina is kept so distended by the back part of the pessary, that, instead of yielding, as before, it bears the fundus uteri upward and forward, throwing the cervix downward in the vagina, and keeping it there. Its advocates allege that its mere introduction alters the position of the uterus from retroversion to that of simple prolapsus in the first degree, and that it is by the distention of the posterior roof of the vagina to its normal dimensions that the organ is kept *in situ*, and not by any force exerted against it; thus avoiding the danger of local injury, while it corrects the displacement. When well adapted to the dimensions of the pelvis and vagina, it is said, it may be worn without annoyance for months, or even years. There is one inconvenience, however, attending its use in some cases, which may, nevertheless, probably be guarded against, viz., the fundus so pressing on the posterior bar of the pessary as to bear up the two lateral bars, and thus their anterior ends excite irritation under the pubic arch. If the fundus uteri be well thrown forward, this objection may be obviated. Perfect rest in bed for a few days, after the reposition of the organ by means of the uterine sound, is all that will generally be necessary to secure this result. The same instrument will serve also for prolapsus, flexions, and anteversions of the uterus—for the latter, made with the addition of a front bar, uniting the anterior ends of the lateral bars, thus forming a parallelogram—although it would seem best adapted to cases of retroversion. Proper perineal support will be necessary in addition, in bad cases. One great advantage this instrument undoubtedly possesses, viz., it allows the free application of injections, &c., to impart strength to the relaxed vaginal walls. This instrument is generally made of silver, and afterward gilded.

Dr. WEST, who has had great experience in the treatment of uterine diseases, remarks (*"Lectures on the Diseases of Women,"* 8vo, p. 413. Lond., 1856. Part I.), in regard to displacements and flexions of the womb, as follows: "Though I have tried the uterine supporter" (SIMPSON'S) "in a few cases, I have now for some time quite given up its employment, and content myself with a mode of treatment which, though it seems to promise less, yet almost always affords great relief—which, in a large number of cases, quite removes the patient's sufferings, and is not unfrequently followed by the complete rectification of the position of the womb. The principle, indeed, on which I act in the management of these cases amounts pretty much to this: that, to the best of my power, I take care of the general symptoms, and leave the misplacement to take care of itself." We are satisfied that, as a general rule, this is the proper course to take; at the same time, it must be conceded that there are exceptional cases in which a suitable pessary may be used with advantage, especially in retroversion, on the principle of supporting or distending the vagina upward behind the uterine neck.]

151. VI. INVERSION OF THE UTERUS—*(the turning of the organ inside out)*—is clearly impossible in the unimpregnated healthy womb. It is one of the most grievous and fatal accidents which can befall a female. My late friend, Dr. CROSS, of Norwich, in his elaborate essay on Inversion of the Uterus, states that of 400 cases of inversion of which he had found mention, 350 were consequences of parturition. Of the remaining

50 cases, 40 were said to have occurred from the presence of a polypus in the interior of the womb, the accident taking place either spontaneously or from traction in attempting to remove the growth. Enlargement of the uterine cavity, associated with some cause exciting contraction of its fibres, are the conditions essential to inversion of the organ.

152. *A.* The symptoms of inversion of the uterus are sudden collapse or sinking, with abundant hæmorrhage, with disappearance of the tumour formed by the uterus in the abdomen, and the presence of a large spherical body either just within the vagina, or projecting beyond the external parts. My friend Dr. RADFORD has, however, shown that, except in cases where the placenta still partially adheres to the uterus, the hæmorrhage is not so formidable as might be anticipated; and that the shock to the system is in great degree independent of the loss of blood.

153. *B.* Inversion of the uterus is caused chiefly by the detachment of the placenta after delivery, owing to undue force or want of care; and, in rarer cases, by a spontaneous and unequal or irregular contraction of the uterus, either while throwing off the placenta, or even soon after, or upon the detachment of it, while the cervix and os uteri are at the same time comparatively relaxed. This explanation of spontaneous inversion of the womb was ably given by Dr. RADFORD, and confirmed by Dr. SIMPSON. The pressure of the bowels on the fundus caused by the action of the abdominal muscles during the detachment of the placenta may also favour this occurrence. A polypus or tumour firmly attached to the interior of the fundus uteri, having descended through the os uteri, may likewise excite irregular action and drag the fundus with it, thereby producing, with varying degrees of rapidity, inversion of the organ.

154. In most instances the inverted uterus becomes speedily firmly contracted; but in a few cases the uterus remains soft and flaccid, and even capable of replacement. The hæmorrhage often continues at short and uncertain intervals, and in very variable quantity from the period of the accident, but to this there are occasional exceptions. The consequences of inverted uterus tend with varying degrees of rapidity to the destruction of life—at least in the great majority of instances. Dr. CROSSE states "that in 72 out of 109 fatal cases, death took place in a few hours, in 8 within a week, and in 6 more within four weeks. The immediate danger, however, being surmounted, there follows during lactation an interval of comparative safety and of cessation of serious symptoms, which reappear when suckling is over. It appears that of the remaining twenty-three patients only one died at the fifth month, and then as the result of an operation which had an unsuccessful issue; one died at eight months, three at nine months, and the others at various periods of from one to twenty years."

155. *C.* The diagnosis of inversion may be overlooked or mistaken. The inverted uterus has even been torn away by ignorant persons who had believed it to be the placenta. Dr. CROSSE considered that the womb may be partially inverted spontaneously a short time after the detachment of the placenta, or depressed at its fundus. This may increase to *introversion*; but the partial inversion, although attended by much vital depression and hæmorrhage, will not occasion

any tumour in the vagina, nor a complete disappearance of that formed by the uterus in the abdomen. Introversion of the uterus may, however, soon pass into *complete inversion*. An inverted uterus may be mistaken for polypus, and a fatal issue result, as indeed it has resulted, from this error. The history of the case generally will assist the diagnosis, but polypus may complicate pregnancy, and may occasion both a tumour after delivery and hæmorrhage. The firm constriction of the os uteri upon the cervix of an inverted womb causes the part to assume the form of a pedicle, thereby rendering the diagnosis more difficult, unless an examination be made *per rectum*, when the uterus, if inverted, will not be found in its place, while, if the vaginal tumour be a polypus, it will be found in its proper place, and probably also somewhat enlarged. The uterine sound, as improved by Dr. SIMPSON, will also aid the diagnosis, if properly used.

156. *D.* The treatment of inverted uterus is attended by great difficulty. If the accident occur before the detachment of the placenta, the removal of this body should be effected before the replacement of the uterus be attempted. Dr. SIMPSON's accurate views as to the source of hæmorrhage in parturition show that fears of serious bleeding in consequence of the removal of the placenta in these cases need not be entertained. Two modes of returning the uterus when inverted after labour have been recommended. The one by pushing back or indenting the inverted fundus with the finger; the other by grasping the womb between the fingers, compressing it, and by pushing it upward into its proper situation. Either of these modes may succeed in recent cases occurring after delivery, while the organ is soft or flaccid, or as long after as it may remain in this lax state. In these cases, as well as in others, in which the replacement is attempted either when the organ is more firmly contracted, or when some time has elapsed from the occurrence of the accident, chloroform may be found of use in facilitating the operation, although in some cases where this substance has been employed no advantage was procured from it.

If the inverted womb cannot be replaced, immediately after the recurrence of the inversion, it will remain irreducible, and entail on the patient all the miseries and perils incidental to this state. The only means of averting these are by operations, which are attended by very serious hazards. The chief reasons which can be urged for such operations—the removal of the inverted organ by the knife or by ligature—are profuse hæmorrhages or discharges endangering the patient's life. Dr. WEST has given the following table of the results in 50 cases of inversion of the uterus after delivery, in which extirpation of the organ was performed.

	Cases.	Recovered.	Died.	Operation Abandoned.
Uterus removed by ligature.....	33	28	5	2
Uterus removed by the knife.....	4	3	1	
Uterus removed by knife and ligature	8	5	3	
	50	36	12	2

157. It is of importance to know the results of extirpation at different periods from the time at which the inversion occurred. If the operation be performed soon after the occurrence of the accident, it cannot be expected to be as successful

as at a remote period from the occurrence, as the organ will diminish in size, vascularity, and sensibility by the lapse of time. Accordingly we find that, of 21 cases thus operated upon within twelve months from the occurrence of the accident, 9 died, and 12 recovered; while of 25 cases in which the operation was not performed until one year, or much longer periods, had elapsed, 23 recovered, and only 2 died. Of the occurrence of inversion from a polypus, and of the various modes and appliances for extirpating the uterus, I must refer the reader to works on surgery, and to those enumerated in the BIBLIOGRAPHY and REFERENCES to this article.

158. VII. OF POLYPI OF THE UTERUS.—Polypi and tumours of the womb generally occur during the period of sexual activity, or, if they be developed at a somewhat later period, or soon after the climacteric period, they have generally originated some time previous to it. It is often very difficult to ascertain the *causes* which either *pre-dispose* to or *excite* their formation; but there is reason to infer that inordinate excitement or determination of blood to the uterus, with a disposition to hypertrophy of one or more of the tissues of the organ, are the chief causes of these lesions.

159. i. *Mucous polypi*, or excreescences from the folds of the *arbor vitæ*, are often met with, varying from a third of an inch to nearly an inch in length to about three or four lines in thickness: they are connected with the mucous or villous membrane of the canal of the cervix by a very slender and short pedicle. They are usually of a bright rose tint, are supplied with a delicate network of vessels, and consist of mucous membrane, with a small admixture of cellular tissue internally. They may spring from any part of the cervical canal; but they more frequently arise nearer to the external than to the internal os uteri. Although generally pediculated, they are sometimes sessile, and in rare cases they seem as hypertrophied folds of the *arbor vitæ*. These productions are either single or multiple, two or three existing in the same patient; and having been removed, they may be reproduced in a few months afterward. They may even coexist with fibrous tumours of the uterus. Dr. MONTGOMERY, of Dublin, believes them to be sometimes precursors of malignant disease; and this was observed in one case which was, under my care. In rarer instances these polypi are much larger than now stated, and consist of a cellular or fibro-cellular tissue invested by mucous membrane; sometimes they reach the size of a fig, are flattened, and hang down beyond the os uteri into the vagina.

160. ii. *Follicular polypi*, or polypi from enlargement of the follicles of the cervix, are not unfrequently observed. They appear as *cysts*, of the size of a pea, imbedded between the folds of the *arbor vitæ*, and hardly projecting beyond the level of the canal. They are, however, sometimes much larger, are more or less numerous, and are distended by albuminous matter. When large and numerous, they cause the absorption of the cervical structure, and even occasion the bulging outward of the structure of the cervix.

161. iii. *Complex polypi*, consisting of mucous follicles, the mucous or villous surface, and fibro-cellular tissue of the cervical canal, are more frequently seen than either of the foregoing. These polypi are either pediculated, the pedicles being

sometimes of considerable length, more rarely very short, or appear as continuous tumours or growths from the inner surface of one or other of the lips of the os. When divided they are found to contain a tenacious, transparent, albuminous matter, identical with that secreted by the Nabothian glands. When small they consist chiefly of cysts filled with this matter. When they are much larger, and reach the size of the first joint of the thumb, these cysts or vesicles are not so distinct, but exist in the form of canals, arranged longitudinally, between which a fibro-cellular tissue enters more or less abundantly. Their surface often presents an uneven or tubulated appearance, is generally not very vascular, and is composed, according to VIRCHOW, of a dense cellular tissue, covered by a thick layer of tassellated epithelium.

162. iv. The *symptoms* indicating the existence of polypi generally appear gradually, and may with increasing severity continue months or even years before medical aid is required. There are usually at first leucorrhæal discharge, hæmorrhage, or both, followed by bearing down pains in most cases. When the polypi are very small, they may produce either very slight symptoms or no symptoms at all. Hæmorrhage is, however, very generally experienced, especially when the polypi occasion enlargement of the neck of the womb. The size of the polypus may not influence the hæmorrhage, a small one often causing more than a large one. Dr. WEST considers that the structure of the polypus influences the symptoms, and that those polypi which present the compound structure due to the enlargement of the Nabothian glands are always productive of profuse leucorrhæa; and their vascularity of surface being less, they are less frequently the occasion of hæmorrhage. The much rarer occurrence of follicular polypi is attended by a profuse albuminous discharge, and is not associated with profuse menorrhagia, unless in rare instances. The symptoms now mentioned should always suggest digital examinations, and if no polypus can be felt, examination by the speculum becomes requisite.

163. v. The *treatment* of polypi is thus described by Dr. WEST: "The smallest may be removed by laying hold of them with a pair of long forceps and twisting them off, while those which are somewhat larger, after being twisted to check the risk of bleeding, may be cut off by a pair of scissors. The bi-valve speculum should always be employed in doing this, and both forceps and seissors are made for the purpose, so constructed as to be readily worked within the speculum." For the sessile growths or tumours, noticed above (§ 159), he applies the acid nitrate of mercury, which destroys them, and arrests the bleeding. As respects the removal of larger polypi and the several means of accomplishing it, I must refer the reader to the work just quoted, or to the surgical works where this operation is fully described.

164. VIII. FIBROUS POLYPI OR TUMOURS WITHIN THE UTERUS are among the most serious organic diseases of the uterus, and the least amenable to treatment. They are uncertain in their rates of progress, being in some cases rapid and in others slow, and in rarer instances almost altogether cured by the efforts of nature, which either throws off the morbid structure from the organ in which it is seated, or stops its growth. These tumours vary much in structure and in their seat. When they arise from the internal surface of the uterus, or underneath the internal membrane, they are

generally considered as a form of polypus, and described as such—as *fibrous polypus* of the uterus. Dr. West considers them to be fibrous tumours, growing from the inner surface of the womb, or less frequently from either lip of the os uteri.

165. *A. Fibrous polypus of the uterus* is nearly identical with other fibrous tumours of the organ, and differs chiefly either in being developed immediately underneath the internal membrane, or in having more or less of the fibrous structure of the womb interwoven with or covering it. Fibrous polypus of the uterus is pediculated, and, growing from the interior of the womb, is more vascular than other tumours of the organ. The pedicle is composed of uterine fibres mingled with more or less dense cellular tissue. A layer of uterine substance is continued a short distance from the pedicle along the tumour, in some cases, or invests it in part or altogether in others. In addition, the polypus is always covered by the internal membrane of the uterus, which becomes firmer and denser than natural, both it and the fibres of the womb being developed with the growth of the tumour. These tumours are generally single, but they are sometimes double, very rarely more numerous. They are of very different sizes, and occasionally remarkably large. They may, in some instances, be enucleated from their coverings; in others their substance is intimately connected with their envelopes. The vascular supply of these tumours through their pedicles is generally small in proportion to their size and to the quantity of blood in their substance. This comparatively small supply of blood, the profuse hæmorrhages they occasion, and the arrest of the hæmorrhage by ligatures around their pedicles, have rendered it very difficult to determine the actual source of hæmorrhage. Dr. West seems to believe that it is rather from the irritated mucous membrane of the uterus than from the surface of the tumour itself that the bleeding flows; and a variety of considerations confirm this opinion.

166. These polypi being generally formed within the uterus, influence the organ in some respects, according to the situation whence they spring. If they arise low down, or in the cervical canal, the tumour soon grows beyond these limits, and, passing down into the vagina, may acquire a considerable size without disturbing the uterine functions. If they arise from some part high up, or near the fundus of the uterus, they often remain until they have acquired a great size, occasioning enlargement of the organ and thickening of its walls, as in pregnancy. But in many cases, before or soon after the tumour has reached the size of an orange, the os uteri gradually dilates, allows its passage through it, and embraces its pedicle. In some cases this result takes place without much suffering; but in others violent uterine action is excited by the tumour, which recurs at intervals, and resembles the pains of labour. The tumour, or polypus, is thereby extruded from the uterus into the vagina; and the irregular contractions of the uterus, especially when the polypus is firmly attached near the fundus, may drag down or invert the organs, as stated above (§ 151). Generally the polypus is detected soon after it has passed into the vagina; but if not detected, and when allowed to remain in this situation, it acquires a large size. I believe, however, that the largest tumours of this kind reach their full size within the uterus. In

a case which came before me, and in which Dr. LEE was consulted, two tumours were thrown off of the size of between two and three pounds each, immediately after passing the os uteri.

167. Fibrous polypi may present œdema of their substance, extravasation of blood into their structure; and having passed into the vagina, they may undergo ulceration, especially if air come in contact with them, or even sloughing. When they are detached spontaneously, or by means which produce firm contractions of the uterus, as in two cases where this was effected by the treatment which I adopted, their pedicles give way, and the whole mass (fibrous structure and envelopes) is thrown off.

168. *B. The symptoms* of fibrous polypi are nearly the same as mentioned above (§ 162)—leucorrhœa, hæmorrhage, and bearing down, [to which may be added enlargement of the uterus, and sympathetic irritations in bladder, rectum, and distant organs.] The hæmorrhage is at first experienced chiefly at the menstrual periods, which are prolonged, or return at shorter intervals, or are more abundant, approaching to flooding, leucorrhœa being present in the intervals. Bearing down is almost constant in some cases, or recurrent in others, with expulsive pains or efforts, when the tumour has far advanced. When these symptoms are present, a vaginal examination should not be delayed. If the polypus have not passed the os uteri, the *diagnosis* becomes very difficult. In these circumstances the uterine sound, as advised by Professor SIMPSON, or dilatation of the os uteri by the sponge tent, as recommended by the same eminent authority, becomes necessary.

169. *C. The treatment* of fibrous polypi has always hitherto been considered as entirely instrumental or surgical. In two cases which I treated, the means employed were strictly medical, and proved in both, within a few hours, successful, the tumours having been extruded through the os uteri by the action of the uterus, and entirely thrown off. In one of these cases the hæmorrhage was excessive. I prescribed immediately the bi-borate of soda in solution, and directed the dose, about six grains, to be repeated every hour or two. A tumour, about the size of a child's head, was soon after thrown off, six or seven doses of the borax having been taken, when vomiting was occasioned; but the hæmorrhage had very much abated a short time before the tumour came away. A day or two afterward hæmorrhage returned, a vaginal examination was made, the os uteri was found somewhat dilated, and another tumour was felt pressing upon the opening. I then requested Dr. LEE to see the patient with me, when the same medicine was given as before, and the second tumour was expelled in a few hours by the contractions of the uterus. The only other case of fibrous polypus of the womb which I have had an opportunity of treating was one of a single tumour of large size; much hæmorrhage had taken place, and I prescribed the infusion of secale cornutum, with as much of the bi-borate of soda as it would dissolve, to be given every hour or two, until eight ounces were taken. Soon after the whole was given the tumour was expelled.\*

\* *Galvanism* may often be employed with success to stimulate the uterus to expel the polypus, or moderate the attendant hæmorrhage, as suggested by Dr. RAIFORD. Experiments made upon the gravid uteri of some of the

170. The operations advised for removing fibrous polypi are by ligature and by incision. Dr. R. LEE records 27 cases of the removal of fibrous polypi of the uterus; nine terminated fatally (WEST). Excision of the polypus has been dreaded in these cases, the risk of dangerous hæmorrhage from the operation having been considered great. VELPEAU, LISFRANC, DUPUYTREN, WEST, [SIMPSON,] and ARNOTT, however, greatly prefer excision to the ligature. VELPEAU found the hæmorrhage troublesome only in two of twenty cases on which he thus operated. "LISFRANC states that he met with but two out of 165 cases, and DUPUYTREN also but two out of nearly 200; while they all refer to instances of phlebitis, or of peritoneal inflammation leading to a fatal issue after the operation by ligature." Torsion and strangulation of the pedicle by compression have likewise been advised for removing fibrous polypi; but they are liable to the same objections as have been urged against the use of the ligature. It is unnecessary to refer farther to the mode of operating by excision, inasmuch as whoever is capable of undertaking the operation requires no directions respecting it, or, if he should, he will find them in Dr. WEST's work now quoted, or in any systematic work on surgery.

[If phlebitis and puerperal fever are liable to result from the use of the ligature in these cases, from consequent sloughing and suppuration, the same results are likely to happen from an empty or exsanguine state of the blood-vessels. We have not the necessary data for an exact calculation of the comparative dangers of each, but such as we have lead us to coincide in opinion with Professor SIMPSON, and prefer excision. It has been suggested that some modification of the *electric cautery* might be substituted for the knife, and thus avoid the risk of consecutive hæmorrhage; but whether it be practicable or not, we have no means of judging.]

171. I may here mention that fibrous polypi may coexist with *pregnancy*, and that, although remarkably small previously to impregnation, they may participate in the development of the uterus during this period. They do not, however, generally produce marked symptoms during pregnancy, nor interfere with its natural course. After the commencement of labour their injurious influence becomes manifest, either presenting a mechanical obstacle to the passage of the child, or giving rise to very serious consequences subsequently, by occasioning dangerous hæmorrhage, or other difficulties. They may also at this time lead to very serious mistakes as respects their diagnosis. The question as to their *treatment* at this time is of no small importance; for excision, however great the hæmorrhage, may be followed by phlebitis, or metritis, or pelvic peritonitis. Therefore, if the hæmorrhage cannot be controlled by opiates and astringents, the ergot or borax may be exhibited, at first singly, and, if they fail, afterward in combination.

172. IX. TUMOURS IN THE WALLS AND EXTERNAL SURFACE OF THE UTERUS.—i. *Description*.—a. These morbid growths are more or less intimately connected with the parietes of the womb, and are in many instances identified with the structure of

the organ. Several tumours are more frequently formed in the same case than one merely; but when thus multiple, "one or two generally outstrip the others in the rapidity of their development, the rate of which, as well as the nature of the symptoms, is greatly influenced by the situation that they occupy." However situated, or however large, uterine tumours are commonly firm, spherical in form, with nodulated surfaces, and their structure is sometimes interrupted by cavities containing fluid, and varies in density, elasticity, and succulency. They are thus well described by Dr. WEST: "On a section being made of any of these tumours, they present great similarity to each other, being composed of a dense grayish structure, intersected by numerous dead white bands and lines, which are almost invariably arranged according to a definite type or plan. In some instances these fibres have a concentric arrangement, while in others they have a wavy distribution, or are disposed around several different centres. Tumours of the first kind are usually remarkable for their hardness, and their small degree of vascularity; they are also contained within a remarkably distinct fibro-cellular investment, are imbedded in the uterine substance, and seldom attain a size exceeding that of a shelled walnut. The other varieties are more vascular, less firm, have a less complete capsule, may occupy all parts of the exterior or interior of the womb, and may grow to a very large size, so as to weigh twenty, forty, or even seventy pounds. Moreover, it happens sometimes that, in the course of their development, two or more tumours coalesce, at least apparently, so as to form a large growth, though on a section it will be seen that the different growths remain distinct from each other, separated by fibro-cellular septa, the remains of the more complete investment by which, when smaller, each was surrounded." (WEST's *Lectures*, &c., p. 267.) When these tumours are seated near to the internal surface of the uterus, or under the internal membrane, the fibres of the womb either passing over the surface of the tumour in some parts, or actually passing into it, they form the fibrous polypi, or internal tumours of the uterus already described (§ 164, *et seq.*). The vascularity of these tumours varies in different cases, and, like the tissues with which they are connected, they are resolved into gelatin by boiling.\*

\* The *microscopic* characters of fibrous tumours are somewhat various. In all we find a large portion of the mass consisting of tissue resembling the tendinous or fibrous, being composed of exceedingly slender, uniform, pellucid filaments, undulating or crooked, more or less perfectly developed, and variously arranged; and this occurs in all parts of the tumour, both in the more homogeneous basis-substance, as well as in the intersecting bands, the microscopic difference consisting only in the less or more regular arrangement of the fibrous structure or appearance of the tissue. But in different specimens, or even in different parts of the same, the tissue appears more or less perfectly formed: so that, while in some distinct filaments or undulating fasciculi may be dissected out, in others there is rather a fibrous appearance than a fibrous structure. Nuclei or cytoblasts are also commonly strewn through the substance of the tumour, the less abundantly in proportion to the fibrous character of the tissue. There are also other elementary tissues mingled in fibrous tumours, as smooth or organic muscular fibres, and these are sometimes so abundant as to justify the name of muscular tumours, as described by VOGEL; and the mingling of the muscular fibres in imitation of the uterus is usual, if not constant. In some specimens *elastic* fibres may be found intermingled with the more abundant fibrous tissue, thus imitating the structure of fascia. As a general rule, the characters of fibrous tumours are modified towards an imitation of tissues in or

lower animals prove very conclusively the power of this agent in producing uterine contraction. These experiments also prove that the influence is greater when one pole is applied to the upper part of the spine, and the other to the uterus, than when both poles are applied to the uterus itself.]

173. These growths may be developed in any part of the walls of the uterus. Sometimes they are formed "immediately beneath the peritoneum covering the uterus, or the first half inch or inch of the ovarian ligament or Fallopian tubes," and are limited to the fundus, or upper part of the body of the uterus, more frequently on its posterior than on its anterior surface. They there generally remain of a small size, and hardly exceed that of a pea or bean; seldom projecting farther than one half of their bulk. In other cases they either grow outward or inward, from the thickness of the uterine parietes, being apparently only attached to them by a thick pedicle, into which some uterine fibres enter. The tumours which grow outward from the uterine walls sometimes attain the size of a large orange, or even a greater bulk; they, unlike the tumours which grow into the cavity of the womb, receive no investment of fibres from the substance of the organ, and are often present in considerable number. Dr. WEST mentions as many as twelve projecting from the external surface, the interior of the organ being free from disease. Wherever may be their origins, these growths tend as they increase in size, with few exceptions, to become pediculated; these exceptions being the firm, slightly vascular tumour, with concentric arrangement of fibres, which remains imbedded in the uterine walls, without projecting either externally or internally. In rare cases, also, the more vascular, elastic, and succulent fibrous tumour is developed in the uterine walls, attaining the size of the foetal head, producing very great enlargement of the organ, and retaining a spherical form. It may be imbedded in the substance of the womb, without projecting more in one direction than in another.

[There is good reason to believe, from the investigations of Dr. BRISTOWE ("Report of the London Path. Soc." for 1853), that all so-called fibrous tumours of the uterus, at least in their earlier stages, before degeneration has taken place in them, are essentially *muscular* tumours—not simply fibrous tumours with a greater or less quantity of muscular fibre mixed up with them, but developments of true and undoubted muscular tissue. Their most usual position, according to Dr. R. LEE's analysis of 74 cases, is the submucous, viz., those projecting into the cavity of the womb; and the pedicles of these are generally situated just below the openings of the Fallopian tubes. The next position in which they are most abundant is the posterior wall and fundus of the uterus; they are rarely situated in the anterior wall, and still more rarely in the cervix uteri.

If we examine fibroid tumours of the uterus under the *microscope*, we discover elongated nuclei imbedded in an amorphous stroma, while the fibrous appearance is scarcely perceptible; in fact, from the analogy they present to the genuine uterine tissue, in the unimpregnated state, they would seem to be homologous rather than heterologous productions. We have already stated that Dr. BRISTOWE regards them as *true muscular tissue*. They are generally but scantily supplied with blood-vessels, and the hæmorrhage to which they give rise is not owing to a laceration of their vessels, but to the irritation and congestion they induce in the superincumbent mucous membrane, which, from the same cause, may ulcerate and slough. In pregnancy, they cause hæmorrhage by preventing the normal development of the organ; hence they are apt to cause miscarriages. As a general rule, however, they produce sterility. Fibrous tumours have not been observed before puberty. Dr. R. LEE states that they are most frequent in virgins, and that they exist in 20 out of 100 middle-aged women.]

174. The influence exerted by these tumours on the womb depends more upon their situation than upon their bulk. When they are seated externally to the womb, and grow into the peritoneal cavity, they often acquire an enormous size, and the womb is much elongated, and even drawn upward into the pelvis, but seldom increased in bulk. If, however, a small tumour be developed in the walls, or within the organ, more or less increase of size will be observed. These tumours reach the greatest size when they are single and attached to the external surface of the uterus. WALTER has described one which weighed seventy-four pounds.

175. *b.* The *ultimate changes* which uterine tumours undergo are interesting, and often tend, under the influence of vital resistance, to a more or less salutary issue. 1st. When the tumour is externally attached to the uterus, its pedicle may become ultimately so attenuated as to be detached nearly or altogether from the womb, especially if it had formed previously adhesions to the adjoining peritoneum; such cases are, however, very rare. 2d. When the tumour is developed internally, or passes into the cavity of the organ, it undergoes the changes and their results already described (§ 166, *et seq.*). 3d. The tumour is sometimes softened, the more liquid parts are absorbed, and either a calcareous substance is deposited, or remains after the other elements are removed; that the former or actual deposit of calcareous matter takes place is evinced by the quantity of the calcareous matter or deposit. This change takes place both in small and in large tumours, and most frequently in those attached to the outer surface of the uterus; but it may also, but rarely, occur in those which are developed internally. Fibrous tumours of the womb were formerly believed to sometimes degenerate into cancer. This change is now considered never to occur. That a tumour, developed in the walls, or attached to either surface of the uterus, may coexist with cancer of the cervix, is possible, and the coincidence has been observed in rare cases.

[Fibrous tumours not unfrequently contain *cysts*, especially those whose texture is not dense; and this may be owing to softening and liquefaction of part of the tumour, with effusion of fluid in the affected part, or to an accumulation of fluid in the interspaces of the intersecting bands. In other cases, where the cysts are of smaller size, and have smooth and polished internal surfaces, it is more probable that their production depends, as PAGET states, on a process of cyst-formation, as in the breast and other organs. Some fibrous tumours are thickly beset with numerous well-defined and lined cysts; in others there is only one large cyst, or one vastly predominating in size over all the others, when it may and has been mistaken for *ovarian cyst*, and the contents discharged by tapping (*Lond. Med. Gaz.*, vol. 37, p. 1022). Sometimes fibrous tumours undergo a *calcareous degeneration*, consisting in an amorphous and disorderly deposit of salts of lime and other bases,

in combination with, or in the place of the fibrous tissue, denoting a loss of formative power in the tumour. Fibrous tumours also undergo sometimes a softening process, with increased vascularity and congestion, and become œdematous; and then, as their tissue loosens, become very soft, or even diffuent, or else break up, and appear shreddy and flocculent. In this state the outer and less softened part of the tumour may burst, or they may separate or slough. BAYLE states that fibrous tumours exist in 20 per cent. of women who die after 35 years of age.]

176 c. The frequency of tumours of the uterus has been very differently stated by writers; but they seem to be, with the probable exception of cancer, the most common of organic diseases of this organ. Mr POLLOCK states that of 583 cases in which the uterus was examined at St. George's Hospital, 265 were diseased, and in 39 of them fibrous tumours existed, and in 38 cancer was found. The statistics of the malady are very unsatisfactory. In 70 cases, in which Dr. WEST examined the uterus of women who died after puberty of other than uterine diseases, 7 presented fibrous tumours of the organ. From these and other observations made by MALGAIGNE, BRAUN, CHARI, and others, tumours of the uterus are observed chiefly between the ages of twenty-four and sixty; and most frequently from thirty to fifty.

177. ii. *The Symptoms.*—Tumours of the uterus are very often not manifested until they reach a large size; and they exist even many years without producing any inconvenience, or being suspected until they are detected after death. The growths from the exterior surface of the womb frequently occasion no symptoms but those produced by them when they reach a great bulk, or when they disorder the sensibility or functions of adjoining parts. But those which are imbedded in the walls of the organ, disturb either the functions or the sympathetic relations of the womb, although their size may be small. It has been already shown that the growths or polypi which occupy the cavity of the uterus, occasion abundant hæmorrhage and other phenomena. (§ 162, 168.) When these tumours are formed after the cessation of the catamenia, the severity of the symptoms they occasion is much less than at an earlier epoch; and when they are developed in single women, the symptoms generally become much more severe after marriage, and they often either occasion sterility, or, if impregnation takes place, abortion. If pregnancy take place in these cases, the puerperal states, as well as abortions, are attended by much greater danger than in the healthy state of the uterus. The symptoms of uterine tumours are most commonly slight at their commencement, and slowly increase in severity. They sometimes, however, are sudden, more especially the uterine hæmorrhages, which recur after intervals, and are more and more severe; but, unless when caused by internal growths, are not followed by leucorrhœa or any offensive discharge. Dysuria, or retention of urine, sometimes suddenly occurs. As the tumour enlarges, pain in the region of the uterus, bearing down, and sense of discomfort in the pelvis, are felt, with frequent calls to pass urine. The character of the pain is somewhat peculiar; it is rather a dull, aching, or gnawing, but constant pain, seldom preventing sexual intercourse; yet sometimes attended by throbbings, or a sense of heat or burn-

ing, or with intense neuralgic pains such as have been already described (§ 7, *et seq.*). When these symptoms are present, the abdomen, especially towards the pelvis, should be carefully examined; and if any tumour be detected, the diagnosis between a uterine and an ovarian tumour should be made.

178. iii. This diagnosis is extremely difficult, and cannot be attempted without a careful examination, first of the abdomen, and next per vaginam, and in both situations. Tumour of the uterus, when so large as to be felt on examining the abdomen, is always firm, frequently nodulated or uneven, seldom mesial, and generally inclining to either side. On examining per vaginam, the tumour, if uterine, rarely draws the uterus upward, unless it be attached near the fundus. It is most frequently seated in the posterior parietes, and is, more especially in these cases, accessible to examination. It is then found to be firm, sometimes uneven, carrying the cervix towards the symphysis pubis, and often more or less retroverting the organ, and often displacing it somewhat from the mesial line. The os uteri is generally small, circular, and healthy; or somewhat hard, or enlarged, or turgid. If the tumour be intra-uterine, or be imbedded in the walls, the uterus will be found larger, heavier, and less moveable than natural, and if it be seated low in the womb, the cervix uteri will not be unlike the form assumed in pregnancy, not unfrequently disappearing, and its lips being thinned. Dr. WEST remarks that an enlarged, heavy, and somewhat hard uterus, coupled with causeless recurrence and frequent return of uterine hæmorrhage, while the os and cervix uteri are healthy, and I might add absence of pain; or but slight pain during coition, are almost always pathognomonic of fibrous deposit in the uterine substance.

179. Tumour of the uterus must be large to be mistaken for tumour of the ovarium. The former is always slowly developed, and rarely rises out of the pelvic cavity; the latter much more rapidly increases in bulk, and when large rises out of the pelvis. The one is hard, and non-fluctuating; the other is softer, and obscurely, if not more manifestly, fluctuating. The ovarian tumour generally attains a much greater bulk than the uterine, is at first more inclined to either side, and is seldom attended by hæmorrhage during its growth; or by retention of urine when largely developed. The cervix uteri is sometimes drawn upward, but is seldom altered; while large uterine tumours are uneven, nodulated, solid, are attended by alteration of the lower segment of the uterus, and by the absence of, or difficulty of finding, the cervix and os uteri, and not unfrequently by retention of urine.

180. The hæmorrhage attending tumours of the uterus may be mistaken for abortion. The patient not unfrequently encourages the opinion of pregnancy from a desire of being in this state, and care should be had not to be thus misled; but to question the patient as to the history of the case, and to examine locally with care and with reference to contingent diseases of the uterus and of its appendages. The frequent recurrence of hæmorrhage, the absence or character of pain, and the state of the cervix and os uteri, will generally guide the diagnosis in these cases.

181. Fibrous tumour of the posterior uterine wall may be mistaken for retroverted uterus, with which, however, it is often associated. It is, nev-

ertheless, of importance to ascertain the nature of the lesion, although but little may be done as regards its treatment. In these cases, a recourse to the uterine sound, when it can be introduced, may aid the diagnosis; but in most cases a diagnosis is most difficult, and sometimes impossible. It is also very difficult to distinguish between cancer of the body of the womb and fibrous tumour of the organ, but this will be noticed hereafter (§ 199, *et seq.*)

182 The occurrence of hæmorrhages, the non-development of the lips of the uterus, and the history of the case, will prevent uterine tumours from being mistaken for pregnancy; for which the expansion of the lower segment of the uterus, and sometimes a sound resembling the uterine souffle, attending the former, may render the diagnosis between it and pregnancy difficult, more especially as the latter may take place during the existence of an uterine tumour. In these, and many other cases of tumour of the uterus, difficulties of diagnosis which need not be more particularly noticed will occur, and which the acumen of the physician will readily overcome.

[We have found the *uterine sound* of Dr. Simpson of very great value in forming a diagnosis in cases of fibrous tumours of the uterus. By it we readily learn if the cavity of the uterus be elongated; and if this be so, and the uterus be found enlarged, heavy, and somewhat hard, connected with the causeless occurrence and frequent return of uterine hæmorrhage, while the os and cervix are healthy, we may very safely conclude that there is a fibrous deposit in the uterine substance. *Reasoning by exclusion* is here of the highest importance, where the question is between uterine and ovarian enlargements—between fibrous tumours and pregnancy, or fibrous tumours complicated with pregnancy; and the use of the sound is often indispensable in order to furnish us the necessary data. Much may be learned from the previous history of the case, and from the equal or unequal density of the tumour. In one case of Prof. Simpson's, which we were requested to examine for the purpose of forming a diagnosis, and which had baffled several physicians, the employment of the uterine sound led at once to the detection of an immense fibrous tumour in the walls of the uterus, which had elongated its cavity to an extent of 8 or 10 inches.]

183. iv. The *prognosis* of uterine tumours is not very unfavourable to the duration of life, at least for several, if not for many years, unless they are very large, or are productive of very serious symptoms, or are associated with pregnancy. In this latter state the abortion they generally occasion, or parturition at a natural period, is often attended by more or less danger. When the tumour is intra-uterine, constituting the fibrous polypus above described (§ 164, *et seq.*), a cure is then generally accomplished. But the other states of the malady do not admit of cure, and not always of palliation, although this latter should always be attempted, inasmuch as it is often to be attained, and nature, in rare cases, seems to effect a cure in such circumstances, especially when the disease occurs at an advanced period of life—the cessation of the menses tending to favour this result. The prognosis may also be somewhat more favourable when these lesions occur in an unmarried female, or in a widow, than when they affect a married female during the epoch of sexual activity.

184. v. *Treatment.*—Although the treatment of tumours of the uterus is chiefly palliative, yet more active means should not be neglected, with the view of promoting the gradual absorption of the morbid deposit. The patient should avoid sexual excitement; if married, she ought to sleep apart from her husband, and be as physically and mentally tranquil as circumstances may permit her to be. Walking much, or standing long, more especially riding on horseback, or even in a carriage, should be altogether avoided; and the recumbent posture adopted as long as possible, and without any intermissions during the existence of uterine hæmorrhage. The bowels ought to be kept gently open by cooling laxatives, and more particularly by such as neither irritate the larger bowels, nor sympathetically excite the uterus. With this intention the carbonates, the tartrates, or the acetates, or the phosphates of the fixed alkalies may be prescribed, either alone or with the infusion of senna or rhubarb, or with the extract of taraxacum. Hæmorrhages are among the more urgent symptoms for which palliation is requisite. These generally at first occur as an excessive menstruation, and recur with each period; and ultimately they often appear intercurrently, or between each period. The means which I have advised above (§ 169) for arresting the hæmorrhage and expelling the tumour when seated within the womb, might prove of doubtful benefit, or even injurious, if prescribed when the tumour is not thus situated, or when seated as described in this chapter. Therefore the recumbent posture, undeviatingly observed, and astringents and refrigerants taken from the commencement of the hæmorrhage, are indispensable.

185. Where there is either pain or tenderness in the lower part of the abdomen on the accession of this discharge, a few leeches may be applied on this part; or a small cupping over the sacrum be ordered; or dry-cupping on this situation may be substituted for it, when the abstraction of blood appears injudicious; but in these cases the modern fashion of applying leeches to the uterus itself should not be followed. The turpentine embrocation may be afterward applied over the hypogastrium. Sedatives and refrigerants should be given with astringents; and if the pain be urgent, narcotics and the other means advised for neuralgia of the uterus (§ 14–17) may be added. The nitrate of potass may be thus prescribed with the liquor ammoniæ acetatis, with the acid in excess, and with the spirit of nitric ether and tincture of henbane; or the hydrochlorate of ammonia with hydrochloric acid, and hydrochloric ether, may be taken in the infusion of cinchona, or simple infusion of roses, in different circumstances of the disease. If the hæmorrhage be excessive, the more energetic anti-hæmorrhagic remedies, as the infusion or tincture of matric, gallic acid, tannin, the spirits of turpentine, the extract of logwood, &c., may be had recourse to. When the patient is anæmic, or when there is a more continued draining of blood, the muriated tincture of iron, with an additional quantity of the acid, will be given with benefit, with the compound tincture of camphor, or with the infusions of calumba or quassia.

186. I have had reason to believe that a judicious recourse to the iodides has not unfrequently been productive of some benefit. The iodide of potassium should generally be preferred, and be conjoined with the solution of potass, or with

Brandish's alkaline solution, or with either of the carbonates; but it ought always to be prescribed in small doses, and be long persisted in. In other, or in anæmic cases, the iodide of iron may be given in sirup of sarza. The bromides of magnesium and of potassium have been considered as being equal, if not superior, to the iodides, but chiefly from the circumstance of their presence in certain mineral springs, as those of Kreuznach, which have been much employed, both internally and as baths and hip-baths daily, in cases of uterine enlargements and tumours, and with apparent benefit in many cases. These waters may be had in this country. M. VELPEAU suggested an operation consisting of the enucleation of fibrous tumours of the uterine parietes by an incision through the os uteri or the lower segment of the womb. M. AMUSSAT performed this operation in 1840, and it has been subsequently resorted to by others—by BÉRARD, BOYER, SIMPSON, and others; and with success by my friend Dr. PANCOAST of Philadelphia, by Mr. TEALE of Leeds, M. AMUSSAT, in two cases, and by M. MAISONNEUVE; but as the number of unsuccessful cases is much greater than that of the successful, and as their details are by no means encouraging, the hæmorrhage and other consequences being alarming, this operation should not be recommended.

187. X. TUBERCULAR DEGENERATION of the *internal surface of the uterus* is sometimes met with, in the form of a dirty yellow matter, closely resembling the substance of a tubercular bronchial gland at an early stage of softening. This matter is about an eighth of an inch in thickness, extends over the whole internal surface, but rarely into the cavity of the cervix, and more frequently into the Fallopian tubes, which it more or less distends, and is sometimes associated with tubercular degeneration of the ovaries. I observed this association in a young lady who died of consumption at nineteen years of age, and who had never menstruated. ROKITSKY thinks that it never occurs primarily in the cervical canal. Upon scraping off this deposit from the internal uterine surface, it is found that the whole of the internal membrane is removed and replaced by it, and that it is closely applied to the proper structure of the organ, which, with its cavity, is more or less enlarged. At an earlier stage the internal membrane is seen to be opaque, more vascular than natural, and to present small yellow spots, which are found to be distinct tubercular deposits when examined by the microscope. This subject has been investigated by LOUIS, KIWISCH, and GEL, the last of whom has furnished Dr. WEST with a table, according to which it appears that in 68 cases this lesion has been observed at all ages, from 10 years to 80; but most frequently from 20 to 50 years of age; and, according to the appearances in 45 cases, the uterus alone was affected only in 1 case; the uterus and tubes in 12; the uterus, tubes, and peritoneum in 19 cases; and the tubes alone in 8 cases.\*

188. The *symptoms* of uterine tuberculosis are amenorrhœa, or dysmenorrhœa, often associated with leucorrhœa—very common phenomena of tubercular phthisis, of which this uterine lesion is

generally secondary, or, if not secondary in very young subjects, at least coexistent with tubercular deposits in the lungs and other organs or parts.

189. XI. FATTY FORMATIONS have been deposited in the cavity of the uterus in very rare instances, and have been thrown off by the contractions of the organ when they had reached a large size. Dr. WEST refers to two instances, recorded by Drs. BUSCH and SEEGER, where this product was expelled from females of the ages of fifty and fifty-three. In one the tumour was the size of the fist, and was composed of fatty matter closely resembling cholesteroline. In the other case the tumour was the size of a child's head, was connected by a broad pedicle with the whole margin of the os uteri. It was removed by ligature; and the patient, who had suffered from menorrhagia for a year previously, recovered. The tumour weighed three pounds and a half, was said to have been an ordinary fatty tumour, having an investment of dense cellular tissue, septa of which dipped into its substance.

190. XII. CANCER OF THE WOMB.—Of CANCER and of SCIRRHUS and other TUMOURS, as well as FUNGO-HÆMATOID, and of other malignant diseases, full notice has been taken under their respective heads. I shall now only briefly notice the malignant lesions which are found in the uterus, and the treatment which has been advised for them. Before the chronic inflammatory states of the cervix uteri were investigated and their consequences shown, more especially by the writings of Dr. HENRY BENNET, several of these consequences were viewed as incipient cancer of this part of the organ; and the mistake was the more readily made as cancer uteri in most cases commences in this part, and often resembles the changes, more especially hypertrophy, hardening, pain, &c., which result from protracted inflammatory irritation. The profession is much indebted to the writings of Dr. H. BENNET, and more recently of Dr. WEST, for the researches they contain into the diagnosis of malignant diseases of the womb by the former, and into the pathology and treatment of them by the latter physician; and I would advise the reader not to be content with the brief view I shall now take of these maladies, but to peruse the more copious details, furnished by these able writers, not only of these but also of other diseases of the uterus.

191. I have defined CANCER, when treating of this malady generally; but much confusion has existed in consequence of the want of precision in the use of this term; for some pathologists have employed it as representing the *genus* of malignant alterations of structure, commencing or manifesting themselves locally; while others have limited it to the carcinomatous state or variety of the genus. The generic definition of cancer given by MÜLLER is as follows: "Those growths may be termed cancerous which destroy the natural structure of all tissues, which are constitutional from the very commencement, or become so in the natural process of their development, and which, when once they have infected the constitution, if extirpated, invariably return, and conduct the person who is affected by them to inevitable destruction." To this definition no objection can be offered, inasmuch as it comprises all the varieties of morbid structure usually denominated malignant or cancerous. Much confusion, however, has arisen from the different terms by which these have severally been denominated, the

\* That this is a rare affection appears from the fact that, among 200 phthisical females, LOUIS only met with three who furnished examples of tuberculous disease of the uterus. When the affection has been accompanied by a discharge, the vagina often presents spots of ulceration, exhibiting a relation analogous to that of the trachea in pulmonary phthisis.]

desire of originating a name, rather than of conveying a precise idea of the thing named, and of adopting foreign terms, being among the *ludibria* to which modern medical writers expose themselves. Cancerous diseases of the uterus, notwithstanding the microscopic researches of those anatomists who have dignified themselves by the name of Histologists, have not as yet been distinguished by any determinate character, by which they can be undoubtedly known under the microscope, as far as the describers of these characters or appearances have furnished us with the means; and this failure of microscopic diagnosis is most remarkably manifest in respect of those lesions of structure which have been viewed as cancerous by some, and which have been as stoutly denied to be such by others, and which are considered by the latter as separate and specific forms of disease, especially epithelial cancer, melanosis, lupus, &c.\*

192. i. FORMS.—Although no form of cancer is peculiar to the uterus, yet they do not all occur with any thing approaching to the same frequency. On this subject Dr. West remarks: "Fungoid or medullary carcinoma is by far the most common; next in frequency may be classed the epithelial varieties of the disease, if indeed it be not more correct, as some men of high authority

believe, to refer them to a separate category distinct from genuine cancer. Next to them, but divided by an interval which widens in exact proportion as fresh evidence is brought to bear on the subject, may be classed scirrhus or hard cancer; while almost as rare, or perhaps even more uncommon, stands the colloid or alveolar variety of the disease." (*Op. cit.*, p. 336.) ROKITSKY says also that fibrous or scirrhus cancer of the uterus is of extreme rarity, while medullary carcinoma occurs with the greatest frequency. This opinion accords with those of Mr. PAGET and Dr. WEST. But Professor KIWISCH states that scirrhus or hard cancer occurs in about three in every ten cases of cancer of the womb; and he remarks, that with the softening of fibrous or scirrhus cancer the characters of this growth gradually disappear, and, becoming more vascular, the mass is more easily broken down, and contains a brainlike substance, the ulcer which forms presenting the same character as those which are observed in medullary cancer. Dr. West states, that of 120 cases of uterine cancer, the disease appeared, from an examination during life, to be medullary in 108, epithelial in ten, and colloid in two; and of 120 cases, the disease occupied the *body of the uterus* only in two.

193. A. It is fully shown that the cervix, or the part of the womb which projects into the vagina, is that in which cancerous disease commences, and that the exceptions to this are very few. The mode of its commencement, however, varies in the different forms. The *medullary* form begins with a morbid deposit in the substance of the cervix, enlarging or thickening it more than elongating. The lips of the os are enlarged, hard, and tense, and, at the same time, irregular, nodulated, and wide or gaping. When the cervix is incised, the structure is occupied by a white, firm, and semi-transparent matter, which seems infiltrated in parts, and has displaced the structure in others. This deposit is more abundant near the internal or mucous surface than near the external. Softening of the diseased part soon takes place, death of the mucous covering follows, and an ulcer, with ragged and uneven surface, and with raised, irregular, hard edges, supervenes, and is covered by a dirty sanies. As the disease proceeds, the lips and cervix are altogether destroyed, and the eroded parts are covered by a soft, dirty white, and often offensive substance. The carcinomatous ulceration may commence either in the softening of the morbid deposit, extending externally or superficially, or in erosion of the surface, the consequent ulceration proceeding more deeply; but the formation of the open sore takes place sooner or later, and advances with very different degrees of celerity; foul granulations and fungous growths spring forth; a fetid pus, mixed with a fetid, greenish-brown, or sanguineous fluid, or bloody débris, or with more or less abundant hæmorrhages, marking the progress and destruction of the lower segment and upper portion of the vagina. In the more retarded cases, cancerous deposits take place in the substance, in the cavity, or on the external surface, and even in the close vicinity, of the organ; and ultimately the disease invades more or less the whole body of the uterus, often extending to the ligaments and ovaries, and sometimes forming malignant polypi within the cavity. Cancerous tumours also form on the uterine peritoneal surface.

[\* Under the article "*Scirrhus and other Tumours*" will be found the histological characters of true cancer, as laid down by BENNET, and to that article the reader is particularly referred. Before referring to the views of PAGET, it may be well to recall the following opinions of VOGEL, as contained in his "*Pathological Anatomy*" (Am. ed., p. 166): "Carcinomatous structures are distinguished from the preceding class, the slightly organized epigeneses" (t. phus and serofulous deposits and tubercle), "by a higher degree of organization; they not only show a more highly developed cellular structure, but frequently also fibres, vessels, and granulations enter into their composition. They are not, however, strictly limited from the former class; for, although the tumour, as a whole, can be easily distinguished from one of the former class, it frequently contains particular portions which cannot be distinguished with certainty from tubercular deposition. *Neither is there any strict limit between these and certain forms of non-malignant tumour, namely, fibrous tumour; and cases frequently occur in which it cannot with certainty be determined whether a tumour belongs to the carcinomatous or fibrous group, i. e., whether it be malignant or non-malignant.* The malignancy depends here, as in the former class, on softening and a disintegration of the elements, commencing with the cellular structures, but gradually proceeding to the fibrous parts, and the elemental tissues of the affected organ. The anatomical and histological relations of carcinomatous tumour exhibit the greatest variety; indeed, even in the same tumour, different parts often present very different characters. Their characters farther vary with their stage of development. These tumours are sometimes soft, resembling cerebral substance; sometimes firm, like lard; and sometimes hard, like cartilage. Sometimes they are highly vascular, and of a reddish tint; sometimes pale; sometimes they are distinctly separated from the adjacent parts, while in other cases there is no line of demarcation between them and the surrounding tissues" (p. 266). We are indebted to Mr. PAGET for a very full and accurate description of the various forms of the true cancer-cell ("Surg. Pathol.," Amer. ed.), and he very truly observes that "the experienced microscopist will very rarely fail in the diagnosis of a cancer by its minute structures; but he only discriminates them as specific modifications of the nucleus, nucleated cell, endogenous cells, and other forms, of which the types are in natural parts" (excretory gland-cells and epidermal cells). He finds among them no new type-forms. Still, this pathologist admits (*Loc. cit.*, p. 354) that there are cancerous tumours which are not composed of the true cancer structures, and remarks that we should do right "to choose modes of life rather than structures for determining the affinities of morbid products, and for arranging them under generic names. As of all tumours, so especially of cancers, the true nature is to be apprehended only by studying them as living things."]

194. *B. The scirrhus variety of cancer uteri* is described by ROKITANSKY as very rarely affecting the uterus, the most common form being the medullary, either by itself or complicated with the former. Fibrous or scirrhus cancer always commences in the cervix, its primary occurrence in the body of the uterus being extremely rare. When closely examined, it appears to consist of dense, whitish, retiform fibres, differing from the healthy texture, and in their minute meshes a pale reddish yellow or grayish translucent substance is deposited. This morbid growth invades the uterine structure, and furnishes no marked boundaries. It is various in extent, and accumulating at certain points, gives rise to irregular, nodulated elevations and indurations, and enlargement of the cervix, or portio vaginalis uteri.

195. Cancerous degeneration of the uterus in either of these forms is generally confined for a considerable time to the vaginal portion; but the disorganization often extends with more or less activity not only to the body and fundus of the organ, but also downward involving the vagina, thus associating with it vaginal cancer. It may even extend in other directions, and thus invade the rectum, the bladder, the cellular and adipose tissues of the pelvis, and at last the ovaries and the peritoneum, cancerous growths either forming upon it, or perforating it chiefly in the state of medullary masses. The destructive process, when extending to the vagina, predominates on either the anterior or on the posterior wall; sometimes to both equally, and occasionally almost to the external orifice. In these cases it often involves the parietes of the bladder and rectum, producing in the most advanced states communications between their cavities, and the most distressing conditions, consisting of a large fungoid cavity, occupying the vagina, the uterine cavity, opening into the cavities of the bladder and rectum, and closed superiorly by the parts agglutinated around the fundus, by the medium of adhesions between the peritoneum covering the adjoining viscera. The formation of these adhesions increases the distressing symptoms of the last stage of the malady.

196. Cancer of the uterus is generally a primary malady, and continues for a long time, if not throughout, the only cancerous affection of the body. It is, however, sometimes developed concurrently with, or consecutively upon mammary or ovarian cancer; or it may be accompanied with or followed by degeneration of the structures just mentioned and of the lymphatic glands. It more rarely becomes associated with cancer of the stomach, or liver; more frequently with that of the mammae and peritoneum, and occasionally with a universal cancerous deposit, or with mollities ossium. Uterine cancer seldom terminates fatally without extending to the upper portion of the vagina. It is commonly allowed that cancer uteri is confined to the part it commences in for a considerable period, and for a longer time than cancer of any other organ. M. LEBERT states that secondary deposits in other parts occurred only in a third of forty-five cases of uterine cancer. Professor KIWISCH found the disease present in the bladder in 42 per cent. of his cases of uterine cancer. But in this, as well as in other diseases, statistics cannot be depended upon, and for reasons I have stated in other places.

197. *C. Epithelial cancer, or Cauliflower excrescence of the os uteri*, and which is doubted by some

to be cancerous, is of very rare occurrence.\* It presents a cauliform appearance, or, according to ROKITANSKY, the appearance of a confervoid growth, consisting of lenticular, pale-red, transparent, and tolerably hard bodies, strung together like the beads of a rosary, projecting on the orifice of the uterus into the vagina, and bleeding on the slightest touch. The only case in which I have seen it came only once before me in consultation, and it then seemed to me as a fungoid form of cancer; and, from the local changes, the bleeding upon examination, and the cachectic and anæmic appearance of the patient, as undoubtedly a variety of carcinoma or cancer. The case observed by ROKITANSKY is stated by him to have grown from an evidently cancerous base of the medullary variety. Dr. J. CLARKE and Sir C. M. CLARKE, who first described this malady, have viewed it as less formidable, and have stated that it is sometimes curable. It is not improbable that the medullary form of cancer of the cervix may present fungoid or confervoid growths, of a cauliflower appearance; and that an intractable but non-cancerous ulcer of the os uteri may give rise to large fungoid granulations, bleeding on the slightest touch, and both lesions may be thus confounded, the former, however, not admitting of cure, the latter in rare cases. Both these lesions are attended by frequent, exhausting, and dangerous hæmorrhages. These morbid growths

[\* According to PAGET only a part of the cases to which the name of "*Cauliflower Excrescence*" has been ascribed have been epithelial cancers; of the rest, some were medullary cancers, and some, perhaps, simple, non-cancerous, warty, or papillary growths. VISCNOW, LEBERT, and PAGET, agree in opinion that there are three different kinds of papillary tumours at the os uteri—the *simple*, the *caneroid*, and the *cancerous* (that is, the epithelial cancerous and the medullary cancerous); the first two forms together constitute the cauliflower growth. This begins as a simple papillary tumour, and at a later period passes into caneroid (epithelial cancer). At first, one sees only on the surface papillary or villous growths, which consist of very thick layers of peripheral flat, and interior cylindrical, epithelial cells, and a very fine interior cylinder, formed of an extremely little connective tissue with large vessels. The outer layer contains cells of all sizes and stages of development, some of them forming great parent structures with endogenous corpuscles. The vessels are, for the most part, colossal, very thin-walled capillaries, which form either simple loops at the apices of the villi, between the epithelial layers, or towards the surface develop new loops in constantly increasing number, or, lastly, present a reticulate branching. At the beginning of the disease, the villi are simple and close-pressed, so that the surface appears only granulated; it becomes cauliflower-like by the branching of the papillæ, which at last grow out to fringes an inch long, and may present almost the appearance of an hydatid mole. After the process has existed for some time on the surface, the caneroid alveoli begin to form deep between the layers of the muscular and the connective tissues of the organ. In the early stages of the disease, the cavities may be simply filled with epithelial structures; there may be, however, alveoli on whose walls new, papillary, branching growths may be seated—a kind of proliferous, arborescent formation. Such is the description of the cauliflower excrescence by VISCNOW, endorsed by LEBERT and PAGET; and, as the last writer remarks, illustrates the usual history of the most exuberant epithelial cancers, the "*simple, papillary tumour*" being an excessive papillary outgrowth of epithelial cancer; the later stage of the same, when it passes into caneroid, being the usual extension of such a cancer into deeper parts—a continuous growth of the same thing in a new direction, inasmuch as papillary structures, composed of epithelial cells with blood-vessels, and a little connective tissue, are the essential characters of the epithelial cancerous outgrowths. Dr. PAGET, indeed, remarks that he believes the same composition has never been seen in any papillary or warty growths that did not, if time were allowed, proceed to the formation of epithelial structures in the deeper parts, and thence through the usual progress of malignant disease.]

consist, microscopically, of "hypertrophied papillæ, composed of epithelial cells, richly supplied in their interior with large and delicate vessels, and covered by a thickened layer of epithelium. The enormous looped capillaries of the cauliflower excrescence explain the abundant hæmorrhages, and the profuse serous discharges which attend it; while the absence of that solid structure which is found in other forms of epithelial cancer accounts for the favourable results that have followed its extirpation.\*"

198. *D. Corroding ulcer of the os and cervix uteri*, first described by Dr. J. CLARKE, begins in the mucous membrane, and involves the whole circumference of the os, utterly destroying both it and the subjacent parts. It differs from cancer in the absence of thickening, hardness, or deposit of heterologous matter, and in its prolonged existence—sometimes for several years without being attended by any dangerous symptoms. It appears to be analogous to lupus, and is more strictly a rodent form of ulcer than a variety of cancer.

[The corroding ulcer of the uterus is a very rare, as well as dangerous form of uterine disease. According to ASHWELL, for one case of it, we meet with 90 or 100 of cancer of the organ. It generally attacks women of spare and lymphatic temperament, and rarely before the age of forty. It may go on from one to five years before it prove fatal; but its progress may be greatly retarded by the use of caustics. The fatal result is at length brought on by repeated hæmorrhage, or by the prostrating effects of the disease. The speculum will usually be necessary to form an accurate diagnosis between it and cancer. Its progress is slower than that of the latter disease, while the pain, discharge, and other inconveniences are generally less. Occasionally, the discharge is very offensive and acrid. The pain and weakness in the back and loins are usually constant and distressing, though sometimes no pain is experienced. The patient gradually emaciates, the discharge increases, with gastric derangement, diarrhœa, or constipation, and in some instances fatal peritonitis results. The disease, in the present state of our knowledge, must be regarded as the result of inflammation of a specific kind. The leading marks of distinction between it and cancer are briefly pointed out by our author. But besides the absence of carcinomatous or other deposit, when examined through the speculum, the surface of the ulcer will be seen to be red, rough, and granular, with a distinct line marking its extent. In cancer, the new deposits and carcinomatous growths tend to fill up the pelvic cavity; in this disease, corrosive action tends to enlarge the cavity. The prognosis in this affection is, in nearly all cases, unfavourable. The general principles of treatment are the same as in cancer uteri.

\* It is the opinion of Professor SIMPSON that cauliflower excrescence, in the earlier part of its progress, is a morbid tissue, but not necessarily of a malignant or carcinomatous character. His chief reasons for this opinion are, its appearing sometimes before the twentieth year; its occasional shrinking and almost total disappearance upon the application of a ligature, or after death; the apparent absence of diseased deposits in the neighbouring tissues and parts upon the dead body; the frequent slowness of its general progress during life; and, lastly, the alleged restriction, and even complete removal of the tumour, in some instances, by the use of astringent applications and other means. Mr. PAGET, however, has conclusively shown that this affection, in every stage of its progress, is generally but a form of epithelial cancer, and consequently malignant, especially in its later stages.]

The nitrate of silver acts very beneficially, by relieving and lessening the quantity and fetor of the discharge. As palliatives, the narcotic sedatives are to be used freely, both locally and generally. The excision of the cervix has been recommended as the most appropriate remedy, especially in the early stage of the disease; but, however much it may promise, there are few patients who will be found willing to submit to it. In some cases, doubtless, it would be justifiable. (For a very full and accurate account of the *Rodent Ulcer*, see "*Lectures on Surgical Pathology*," p. 588. By JAMES PAGET, Philadelphia; 8vo, 1854.) It will suffice to state it is of irregular shape, generally tending towards oval and circular; the base deeply and unequally excavated, not warty, nodular, nor granulated; in these respects, contrasting with cancerous growths. It is also comparatively dry and glossy, yielding, for its extent, little ichor or other discharge, and has commonly a dull reddish-yellow tint. Its border is slightly, if at all, elevated; the adjacent skin appears quite healthy; the base and border feel alike tough and hard, as if bounded by a layer of indurated tissue about a line in thickness. In corroding ulcer, we see more destruction; in cancerous, we see destruction with more than commensurate growth; with the microscope we see no structure resembling epithelial or any other form of cancer.]

199. ii. SYMPTOMS OF CANCER UTERI.—The symptoms which are most constantly observed in cancer uteri—namely, pain, hæmorrhage, and vaginal discharge—may attend other lesions of the organ; but in all cases where they, or even any two of them, are present, a careful vaginal examination ought to be made.—*a. Pain*, accompanied with hæmorrhage or leucorrhœa, is a very frequent, but not a constant, symptom. It varies much in character and intensity, both at the commencement and in the course of the malady; and very often, when the hæmorrhage is profuse, but little pain, or merely a backache, is felt. At an early stage the pain is generally not severe, nor is it always referred to the uterus, but more commonly to the loins. The organ is seldom tender to the touch, and sexual intercourse is not often productive of suffering. The pain, as the disease advances, is referred to one or other of the iliac regions, and either comes on, or is exacerbated in paroxysms, and a lancinating pain referred to the uterus occurs suddenly and at intervals. Menorrhagia may be either attended, or not attended, by pain. In many cases it is, when very profuse, followed by severe pain. With the progress of the malady the pain generally becomes more severe; but towards the close, when the cachexia and anæmia are most remarkable, the sufferings of the patient generally abate more or less. But before this ultimate stage appears, pain in the uterus is added to that in the back and hypogastrium, and to the other distressing symptoms experienced. The pain is, in some cases, described as burning, darting, cutting, &c.; and it is generally aggravated into intolerable paroxysms, especially towards or during the night, stabbing or lancinating pains recurring after short but irregular intervals. When an attack of hæmorrhage supervenes on severe pain, some degree of relief is sometimes afforded for a short period. As the disorganization extends to the bladder, the vagina, or rectum, or even to them all more or less, the sufferings of the patient are accordingly in-

creased; and when utero-vesical fistula is formed, the distress is farther aggravated, and rendered still more harassing. In a very few cases, however, the disease runs its course entirely, or almost entirely, without pain. But it is not so rare for pain to be absent through a great part of the course of the malady, and appear only at a far-advanced period. The absence of pain throughout the disease, or until an advanced stage, occurs chiefly in the epithelial and medullary forms of cancer uteri.

200. *b. Hæmorrhage* is the next symptom in importance, but is not always a sign of the commencement of the ulcerative stage of cancer uteri; for it is, in a very large proportion of the cases, the earliest sign, preceding, and unattended by, either pain or watery, offensive leucorrhœa, for a longer or shorter time. The occurrence of hæmorrhage, whether with or without pain, without any sufficient cause, should always induce to a vaginal examination. The bleeding may not be profuse, but continuous and prolonged, or resemble the ordinary menstrual period, excepting only its non-occurrence at the proper period, or its frequent recurrence. It sometimes assumes this character in females past the catamenial epoch of life, and in whom the menses had ceased for a longer or shorter time. When it thus appears, the existence of the malady should be suspected. When cancer uteri commences at an early period of life, the hæmorrhage most frequently occurs at the menstrual periods, or a day or two after their cessation; but menstruation is generally irregular during the course of the disease, being either too early, or passing over a period, the next being excessive. With the progress of the malady, pain is generally added to hæmorrhage. The source of this discharge appears to be chiefly the internal surface of the cervix and body of the womb; for the hæmorrhage may be excessive before ulceration has taken place, and even when this has undoubtedly supervened, the bleeding may still proceed from the surface of these parts, rather than the ulcerated part; for in many cases this discharge has been the least where the ulceration has been the greatest, and proceeded the farthest. The paroxysmal expulsive pains often attending the hæmorrhage are usually due to the efforts of the womb to expel coagula formed within it.

201. *c. The leucorrhœal discharges* differ in the forms and stages of cancer uteri. A mucous or mucopuriform discharge is frequent at an early period, and is then generally not offensive. But as the malady advances, it is commonly more or less offensive, and it becomes more watery, or appears as a dirty and very offensive sanies. An offensive discharge may accompany any of the chief organic lesions of the uterus; but, although it may exist in these, it seldom occurs in so marked a manner as in cancer. The continuance, the quantity, offensiveness, and other conditions of the discharge depend upon a variety of circumstances—upon the stage and form of the malady, upon the extent to which ulceration has advanced, upon the retention or non-retention of the morbid fluid, upon the frequency of its removal by injections, hæmorrhages, &c. In a few instances, an offensive discharge has preceded either the pain, or the hæmorrhage, or both, although much more rarely; and, still more rarely, this has existed for so long a period, and has given rise to so little suffering or cause of com-

plaint otherwise, that when at last recourse to medical aid has been had, the cervix uteri has been destroyed, and the finger has passed into the cavity of the organ.

202. These symptoms, the most severe which attend cancer uteri—the pain, the hæmorrhage, and the offensive leucorrhœa—cannot undoubtedly prove the existence of the malady. They may individually, or even conjointly, attend other organic lesions of the uterus. But viewing them severally and in connexion with the evidence furnished by a vaginal examination, and with the constitutional symptoms characterizing the course and the advanced stage of the malady (see *art. CANCER*, § 20, *et seq.*), especially the cancerous cachexia, the existence of cancer uteri cannot be mistaken. The remarkable disorder of the digestive organs, the impaired assimilation, and the waste of the red globules of the blood, and even also of the tissues, and the consequent cachectic or cancerous anæmia; the frequent recurrence of disorder of the bowels, more especially of diarrhœa, with both abdominal and hypogastric pains; the distress often caused by defæcation, and more particularly by the state of the urinary organs, and by the urinary discharges, are all indicative of the nature of the malady.

203. Cancer uteri does not prevent a female from becoming pregnant at an early stage of the malady; but the process of parturition, and the changes in the uterine organs and in the female economy that follow, generally accelerate, often with great rapidity, its course. Parturition, owing to the effect of this act upon the diseased parts, especially the cervix, often is accompanied by dangerous hæmorrhage, or followed by severe or fatal inflammation. In some of these cases, both mother and child have died before delivery has been accomplished; generally the process is difficult and prolonged. In some cases, gestation is also prolonged beyond the natural period, and, in rare instances, death has occurred without the efforts of the uterus having been sufficient to expel the fœtus.

204. Dr WEST has given, in his interesting lectures, a table of the result of seventy-four cases of cancer of the cervix uteri *complicating labour*; and of these 41 died soon after labour, and 33 recovered for a time from the effects of this process. Of 72 children, it is stated that 47 were dead-born, and 25 born alive. He found that the average duration of 17 cases of cancer uteri, which he carefully observed, was 15 months; and that of 39 cases, as given by LEBERT, was 16 months. It is thus apparent that cancer uteri is more rapid in its progress than cancer in other organs. The average duration of all forms of cancer is stated by this writer to be 18 months, and of cancer of the mamma and of the testis, the most prolonged, not to exceed three years and a half.

205. *iii. THE PROGNOSIS* of cancer uteri may be inferred from what I have stated above, and in the article CANCER (§ 20–22). ROKITSKY remarks that “cases of spontaneous recovery from uterine cancer are of extreme rarity, but they do occur; the carcinoma and the cancerous ulceration are then limited to the cervix, the internal orifice forming the boundary. The loss of substance heals with a funnel-shaped cicatrix” (*Op. cit.*, p. 303.) In a case, the progress of which was constantly observed by me, recovery took place while a diet and regimen, hereafter to be no-

ticed, was strictly observed. The cicatrix, which was formed low in the vagina, was shaped as ROKITSKY has described it—not more than half an inch of the vagina above the urethra having been left uncontracted.\*

206. iv. CAUSES OF CANCER UTERI.—These are the same as have been stated respecting cancer in general. But there are certain particulars which require notice with reference to this malady, when originating, as it commonly does, in the neck of the womb. The mortality of cancer in females is nearly three times greater in London than in males, and more than double the number of the deaths from cancer in males throughout England; the excess in females being evidently due to the frequency of cancer of the womb and of the breast among them. According to TANCHOU, the deaths from cancer of the womb, stated in the Mortuary Registers of Paris, as compared with those from cancer of the breast, were as 2½ of the former to 1 of the latter.

207. Age manifestly predisposes to cancer; but this disease appears to occur at an earlier period in the uterus than in the mamma; for in the latter it is rare at the age of thirty, whereas it is not so rare at this age in the former situation. Cancer uteri increases in frequency with the advance in life, as Dr. WALSH has shown: but in order to render the increase more manifest, the number of cases at a given age should be calculated with reference to the number of females supposed to exist at the same progressive periods of life. The inference deducible from this fact is, that the occurrence of cancer is in some degree favoured by the depression or exhaustion of vital power taking place from the progress of age, as well as from other causes of vital depression.

\* Mrs. C.—, at the age of 36, first complained of symptoms indicating an early stage of cancer uteri. The disease advanced, and several medical men were consulted at her own or my suggestion. The cervix had become much affected, and the disease extended far down the vagina with distressing irritability of the bladder. At this time she found Dr. LAMBE's work on "*A peculiar Regimen, &c., in the Treatment of Cancer, &c.*," in my library. He was consulted in her case, and he recommended her to remove to a dry and healthy locality in the vicinity of London, to strictly observe a vegetable diet, to drink only distilled water, and use only distilled water in cooking and for infusing tea or other substances. These injunctions were observed without any deviation, and under his supervision. In the course of a few weeks amendment was very apparent, and in somewhat less than twelve months a cicatrix, as situated and described above, was formed. The patient continued this regimen for nine or ten years, and enjoyed excellent health. After this period she began to partake of fish, the flesh of chickens or rabbits, &c. She afterward ventured farther upon animal food, and occasionally took a glass of old wine. Five or six years more elapsed, when she complained of the right mamma, and when examined the disease was commencing in it; but no complaint was made of the parts in the vicinity of the first disease. The diet was now altered, but the malady proceeded slowly; and having been unusually prolonged, extended inward, affected the pleura; and ultimately the vaginal cicatrix was attacked, and she ultimately sunk, more than twenty years from the commencement of the malady in the cervix, and after an interval of nearly fifteen years of good health.

[In the *American edition* of Dr. LAMBE's work, on "*Water and Vegetable Diet in Chronic Diseases*" (12mo. New York, 1855), there is the history of another remarkable case of cancer uteri, attended with an acrimonious and offensive discharge, where the pain, discharge, &c., were subdued, and the general health and comfort of the patient greatly improved by the use of a strictly vegetable diet, without medicine, except opium. The disease, at the time of the report, had been controlled for the space of twenty-five months, without making any perceptible progress, while the ulcerative process had been wholly superseded.]

Dr. WEST has given a table of the ages of 426 cases of cancer uteri, collected from various sources:

	Actual Number.	In the proportion of 1 to 10,000 of the whole population existing at the respective ages.
Between 25 and 30 years	25 or	1 in 134
" 30 " 40 "	112 "	1 " 21
" 40 " 50 "	178 "	1 " 9.7
" 50 " 60 "	71 "	1 " 16.6
" 60 " 70 "	35 "	1 " 23.6
Above 70 "	5 "	1 " 108.

From these data it would appear that, although cancer uteri becomes more frequent as life advances up to fifty or sixty, it diminishes considerably in frequency from these ages; and from this table, as well as from other sources of information, it cannot be inferred that the actual cessation of the catamenia has any influence in favouring the occurrence of this malady in the uterus. Dr. WEST justly remarks that the state of the uterine functions previously to the appearance of cancer is not without interest; and he adds that, in 108 cases, this matter was made the subject of special inquiry. In 94 cases these functions were in all respects natural from their complete establishment to the commencement of the disease; and in 14 they were either habitually or frequently unnatural, being painful, postponing, or irregular. Out of 116 married women affected with cancer uteri, only 7 were sterile. The hereditary predisposition to cancer has been well established, as shown in the article on CANCER (§ 23). Mr. PAGET found that this malady in all situations was hereditary in the proportion of one to 6.1; Mr. LEBERT, in the ratio of one to 7.2; and Dr. WEST in 1 to 6.2. The proportion of hereditary cases is very probably higher than here stated, as it is difficult to ascertain from the patients the nature of the disease which caused the death of either, or of both parents.\*

208. v. TREATMENT OF CANCER UTERI is necessarily confined to palliating the suffering of the patient, and to attempts at delaying the approach of death. The symptoms which more especially require mitigation are *hemorrhage*, *pain*, and the *offensive discharge*. The means which should be resorted to for the first and second of these have been fully described in the articles HÆMORRHAGE, NEURALGIA, and CANCER; but there are a few topics connected with the treatment of cancer affecting the uterus, and of the effects of this malady, which require farther consideration.

209. a. *Hæmorrhage* is among the earliest and most alarming symptoms of cancer uteri. The obvious intention is to abate it when severe or too frequent, and to prevent its recurrence altogether, or before the catamenial period. The various means usually employed for *hemorrhage from the uterus* have been detailed (see art. HÆMORRHAGE, § 263-273); but there are a few of these which require a more particular notice at this place. The *gallic acid*, in doses of six to eight grains of every four or five hours, have been often found of decided service in arresting the hæmorrhage. The infusion of *matico*, used as an

\* I have noticed the question "Is Cancer contagious?" when treating of SCIRRHUS AND OTHER TUMOURS (§ 79, 80), and have referred to cancer, one of which was under the care of the late Mr. MAYO and myself, in which cancer of the glans penis in the husband communicated the disease to the cervix of the uterus. I have there stated my reasons for inferring that the disease may thus be communicated to the wife by the husband.

injection into the vagina, is also very efficacious. Dr. WEST states that, in some cases of medullary and of epithelial cancer, when the hæmorrhage is excessive, or prolonged, the morbid tissue may be broken down with the finger, and the tincture of the *sesquichloride of iron* injected into the midst of it. The extravasated blood is thereby coagulated, and the vessels destroyed, the whole mass thus treated sloughing away. KIRWISCH, who first resorted to this practice, remarks that it is not attended by much pain or serious constitutional disturbance. He also advises a recourse to the actual cautery, where the surface is too firm to be broken down. In one case, after other means had failed, I recommended the injection of the spirits of turpentine, in the manner in which the tincture of the muriate of iron has just been advised, the same medicine being given frequently by the mouth in small doses; and the hæmorrhage was for the time arrested. It is obvious that sexual intercourse is liable to occasion an attack of hæmorrhage, and that it should therefore be strictly forbidden whenever cancer uteri is suspected.

210. *b.* Pain is often so excessive as to require energetic means of relief; but, as long as it is not acute, the gentler remedies only should be employed. The pain is sometimes brought on, or aggravated by an irritable state of the bladder, or by the condition of the urine, and not unfrequently by neglect of the functions of the bowels. Therefore the states of both the urinary and fecal evacuations should receive due attention. The former may be corrected, and the irritable condition of the bladder mitigated by the exhibition of the solution or the bi-carbonate of potash with tincture of henbane, or by the mineral waters of Ems or of Vichy. If the urine abound in the phosphates, the means I have advised for this condition, when treating of the morbid states of the URINE (§ 90, *et seq.*), especially the hydrochloric acid taken in the decoction of pareira, or in the infusion of buchu, may be prescribed. The bowels may be regulated by means of the gentle cooling aperients ordered above (§ 184).

211. When the pain becomes so severe as to require anodynes, then plasters of opium or belladonna may be applied over the sacrum or above the pubes; and chloroform may be tried as an epithem, by means of spongio-piline. Internally the pilula saponis cum opio, or tincture of opium, may be given at night; and if these occasion neither headache nor sickness in the morning, they may be continued without increasing the dose. The preparations of morphia, unless conjoined with aromatic stimulants, often cause unpleasant depression. The black drop and Battley's sedative solution are often preferred to other opiates, but they are efficacious chiefly in their more powerful narcotic effects, the subsequent distressing sickness, &c., being not less complained of. Henbane and conium are often employed. The former, without alleviating pain, or with slight alleviation only, often affects the head, occasioning restlessness and headache. I have, however, found the two conjoined with camphor—three grains each of camphor and of the extracts of henbane and conium, being more or less of service. Dr. WEST says that after henbane he generally makes trial of the Indian hemp; for, although it is an uncertain remedy, it does not disorder the stomach, or occasion headache. But I have not always found it so pleasant in its ul-

mate effects. In severe paroxysms of pain, the inspiration of the vapour of chloroform has been resorted to; but the relief has been only very temporary. I have in a few cases directed the application of the tincture of belladonna to the diseased part, in the manner advised and resorted to by the late Dr. MOORE (§ 15), with very marked relief. Taken internally, belladonna seldom affords much relief, unless in large doses, which are usually followed by much depression, unless they are conjoined with aromatic stimulants; and these latter often fail in correcting the evil.

212. *c.* The *discharges*, owing to their great excess, or their very offensive odour, require, besides the usual attention to cleanliness, the means which have been advised for the more severe cases of LEUCORRŒA, more especially the infusion of matico, or tannin; the decoctions of oak-bark, of buchu, of cedar-bark, or of pomegranate-bark, &c. Weak acid lotions, and various other astringents, have also been recommended. Dr. WEST mentions the use of an injection of ʒj. of sulphate of iron, and ʒij. of the extract of conium to a pint of water; and he adds that a solution of ʒj. \* to ʒss of nitrate of silver to an ʒj. of water, injected immediately into the diseased structure, has the effect of hastening the separation of the slough and of destroying the bad odour. I have most frequently employed, for these purposes, the chloride of lime, or creasote, or both, in injections, consisting chiefly of mucilaginous fluids, in quantity and frequency according to the progress and urgency of the case. When the disease was very far advanced, and the use of these appeared likely to occasion inflammation of the peritoneum or adjoining parts, I have preferred to have recourse to powdered carbon, with tincture of belladonna, or extract of henbane, mixed in any mucilaginous fluid, as a vaginal injection. It has generally the effect of deodorizing the discharge and soothing the pain.

213. *d.* The *complication of pregnancy* with cancer uteri must be treated according to the peculiarities of each case, but its treatment cannot be entered upon at this place. It is fully considered in Dr. WEST's work, already referred to, where the reader will also find the results of extirpation of the uterus and of its cervix very sat-

[\* Dr. ASHWELL strongly recommends a strong solution of *nitrate of silver* (80 grs. to ʒj. of water), applied through a speculum, with a hair pencil, or tow fastened to the end of a piece of cane, smearing carefully the affected parts. It rarely produces much pain, being quickly decomposed by contact with the fleshy cervix. The eschar is usually detached about the third or fourth day, being thrown off in shaggy films, when the abraded surface will have acquired a redder and healthier aspect. The caustic should be early repeated, and if, after the fresh eschar, there is still further topical improvement, the treatment should be persevered in; and Dr. A. thinks that a "hopeful prognosis may be given," as often after these renewed applications, extending over many weeks, and aided by the *black wash* or *oxide of zinc*, he has "healed abrasions and commencing ulcerations of the os and cervix." We think it very doubtful, however, whether these were cases of true cancerous disease. From considerable experience in the treatment of this disease, we prefer very much the nitrate of silver to any other local application. The other caustics, as *corrosive sublimate*, *chloride of zinc*, *arsenic*, *nitrate of mercury*, &c., are apt to cause heat, pain, tension, and inflammation, and some of them cause dangerous constitutional effects from absorption. However beneficial the actual cautery may have proved in such affections, the prejudice against it in this country will effectually preclude its employment. The practitioner need not be cautioned in regard to the danger of a hasty diagnosis, few ulcerations or hardenings of the cervix uteri being malignant, although attended with hæmorrhage and other doubtful symptoms.]

isfactorily discussed. To this work, and to surgical writings on this subject, I must refer the reader.

214. *e.* The constitutional treatment of cancer uteri, or the means most appropriate to the existing cancerous cachexia, is not different from what I have advised in the articles on CANCER (see § 27, 44), and on SCIRRHUS GROWTHS (§ 113, *et seq.*). The chief objects proposed are to promote the digestive and assimilating processes, and to support constitutional power, and vital resistance to the progress of the malady. Subordinately to, and forming a part of these, may be mentioned, due attention to the secreting and excreting functions, and the alleviation of the more distressing symptoms. The anæmia attending the advanced stages of the malady should also claim our attention; and chalybeate preparations, and ehalybeate mineral waters, ought to be conjoined with such other means as the circumstances of each case will suggest.

215. *f.* In respect of *diet* and *regimen*, little need be added to what has been already stated in the places just now referred to. A digestible and nourishing food, in moderate quantity, and a temperate and dry air, are generally beneficial. It has been questioned whether much, or even any, animal food be of service, or rather, whether it be not detrimental in this malady. This matter has been fully and ably discussed by my late friend, Dr. LAMBE, a very learned physician, and an original thinker and observer. He imputed this malady, as well as scrofula, gout, consumption, and some other chronic diseases, to the use of animal food and to impure water; and advised vegetable food of all kinds in sufficient abundance, and distilled water for all purposes of internal use, and exercise in a dry and open air, to be resorted to for the cure of this as well as of those diseases. He did not believe that, when cancer was far advanced, this diet could then effect a cure, but he recommended it to be tried; and, at the same time, all fermented and distilled liquors, or other beverages than distilled water, to be relinquished. This diet and regimen were employed with apparent success, as long as it was strictly adhered to, by a married female, whose case I have briefly noticed in a note at p. 1407, § 205.

[Some farther remarks in regard to *cancer uteri* may not be out of place. Although it is generally conceded that confirmed carcinoma of the uterus is incurable either by surgical or medical remedies, yet we agree with ASHWELL, BOUILLAUD, and BRESCHET, that much may be done by a very early, well-sustained, and persevering prophylactic management. It is undoubtedly true, as stated by ASHWELL, that scirrhus or hard tumours of the womb are sometimes cured or become innocuous by altered nutrition, the indurated masses being deprived of their softer cellular tissue, and being converted into cartilaginous, cretaceous, or calcareous concretions. It may, however, be objected that such cases were not true carcinoma; and those who take the ground that cancer is never cured will, of course, assume that such was the fact. But this is a point which yet remains to be established by farther observations. Admitting that in these instances the disease was true carcinoma, it yet remains to be proved how far remedial measures had any thing to do in the cure or recovery. Our views on these points will be in accordance with

our pathology. If, with BOUILLAUD, we regard cancer merely as the result of inflammatory induration, or, with BRESCHET and BICHAT, as resulting from some error in the "organic sensibility," we shall, *a priori*, come to the conclusion that it is a curable disease; and this opinion will not be abandoned until multiplied and uniformly unfortunate experience brings us to a contrary conclusion. We are, however, unwilling, from other considerations, to admit that cancer is always an incurable disease. Facts do not warrant such a conclusion. It has been truly remarked, that no malady can be cured by those who are determined to regard it as incurable. Diseases so regarded must be left, as cancer generally is, to quacks and quackery—to those who promise any thing and every thing for money. It is not long since tubercular disease of the lungs was regarded as incurable, and this class of patients were assigned to the tender mercies of empirics. Cancer is sometimes said to be hereditary, but in all cases it is a declaration of the impression of long-standing and injurious influences. Some of the secretory or excretory organs are at fault. There have been some serious errors in diet and general hygienic measures. The treatment is to be based on a most careful investigation of all the functions of animal and organic life, and the influence exerted upon them by the previous habits, mode of life, food and drinks, &c., of the patient. The late Dr. TWITCHELL, of New Hampshire, was cured of an epithelial cancer of the face by confining himself strictly to a diet of bread and milk. We have seen true carcinoma of the breast remain dormant for years by allaying the fears of the patient, and by a course of strict dieting and attention to the excretory organs. A tumour having all the characters of true carcinoma will, under such management, not unfrequently become absorbed, and its elements, doubtless, eliminated from the system. At first, we see the tumour become loosened as to its subjacent connexions, a tucked-in nipple resumes its natural appearance; it loses its characteristic stony hardness by a process of gradual absorption, until at length no vestige of the disease remains. We have witnessed a case in point recently in a near relative. PAGET has truly observed that a cancer adds a new element of disease to those that were already in progress, and that if we assume a constant process of nutrition in cancers, it cannot but be that the blood will be affected both by what they take from it and by what it derives from them in the process of nutritive absorption. What returns to the blood must necessarily be morbid, and exert a very injurious influence upon it, even if incapable of being developed into cancer. Hence the importance of its early and thorough elimination by an active condition of the liver, kidneys, and skin, together with the alimentary canal, the greatest and most important emunctory of the whole body. Here we have the secondary poisoning of the blood superadded to the original cancerous cachexia; and no wonder that, with the cancerous material circulating in the blood of every organ, the disease returns after the original tumour has been removed. After the disease has progressed to the stage of ulceration, with pain, hæmorrhage, discharge, hectic, with a poisoned condition of all the circulating fluids, and a general cachectic state, with a despairing state of the mind, the situation of the

patient may well be regarded as hopeless, although the local disease be removed. But even here the case is by no means to be abandoned. Here come in the palliatives described by our author, which are of great service in alleviating the sufferings of the patient. But many facts go to show, as PAGET remarks, that "not only the progress of the peculiar constitutional part of the disease is nearly independent of the local part, but also that the constitutional part generally contributes most to the fatal issue" (p. 667). And again (p. 525), "The removal of the local disease makes no material difference in the average duration of life." If so, then our remedies must be general, and not merely local. ROKITANSKY has observed that spontaneous natural processes of healing often occur in even medullary cancer, one of the most fatal of all cancerous affections; and PAGET admits that "a medullary cancer may gradually decrease, becoming harder, as if by shriveling and condensing, and at length may completely disappear. I have seen," he remarks, "the same happen after partial removal of cancers." He also speaks at length of the degeneration of cancers, so as to be incapable of increase, or, to use a term of ROKITANSKY, applied to the same structures, "obsolete." WALSH states that "we need not wholly despair, after the removal of encephaloid;" and that "M. VELPEAU has excised well-marked specimens of this species, and seen the patients in perfect health two, four, six, and in one case ten years afterward." Sir ASTLEY COOPER thinks that scirrhus does not return in one fourth of the cases of removal; Dr. J. C. WARREN, that one case in three is cured; and Mr. TRAVERS states that "recovery generally ensues when the disease is removed before the supervision of pain." Professor MEIGS remarks ("Females and their Diseases." Phil., 1848, p. 274) that he has seen "a cancerous mamma as hard as cartilage ulcerated, and firmly adherent, that was totally removed by absorption in a long paraplegia." The results of Dr. GROSS's investigations in regard to the curability of cancer are, however, more unfavourable (*Trans. of Am. Medical Association*, 1854).

But in considering the question of the curability of cancer, whether of the uterus or any other organ, we are to remember that "it is an organ," as SIMON expresses it, "for excretory purposes" (*General Pathology*, 8vo. Phil., 1852), and that this eliminative effort has its root in some peculiar condition of the general system, called cancerous cachexia, the essence of which we by no means understand. Why it is that the blood sets about constructing an organ, so to speak, for the appropriation and discharge of its own blastema; why the secretory and excretory organs are not adequate for the elimination of those products which result from the disintegration of the tissues, and, indeed, whether, by the influence of secretory and excretory stimulants, alteratives, and a regular diet, such products may be wholly eliminated, are questions which, for the present, must remain undecided, and probably will remain so until we fully understand the chemistry of cancerous bodies and of the whole body, together with those natural changes which take place in the progressive and regressive metamorphoses of the blastema of the blood. We believe, with SIMON (*Loc. cit.*), that the more the nucleated fibrous material abounds in a cancerous tumour, the less

malignant it may be regarded, and the less likely to return if removed by the knife; for all pathologists agree in the opinion that fibrous transformation, so far as it extends, illustrates the operation of common, not of specific developmental influences in the part, just as, on the other hand, the compound granular corpuscles constituting the yellow softening material in cancerous growth represent, as VIRCHOW maintains, the degeneration of cells, and, consequently, a retrogressive tendency in the effusion where they occur. If we assume that the unknown albuminiform material of cancer requires a special cell-growth for its elimination, and cannot avail itself of any known cells for its removal, then our prognosis must necessarily be unfavourable as regards a cure; but as cancer-cells have their analogues in the normal cells of other tissues (as the excretory gland cells and epidermal cells), we may reasonably conclude that, under the influence of special stimulants and proper ingesta, the latter may perform the function vicariously assumed by the former.

If cancer, then, is to be treated successfully, the treatment must be founded on the pathology above indicated, viz., that the disease is a local manifestation of certain specific morbid states of the blood; that it is both a constitutional and local disease, specific in the sense that it depends on some peculiar material in the blood, different from all others, normal or abnormal, and presenting structures, to some extent at least, specific and peculiar, both in form and mode of life; and the cancerous diathesis or cachexia, as consisting in the accumulation of such materials in the blood, while accidental circumstances determine its localization.

SIMON has truly remarked that all cancerous diseases have a chronic period of latency, during which their cachexia acquires intensity from accumulation, till at length it suffices to establish the local vent; and we may argue farther, that the disease can be again reduced to this state of latency and to the accompanying difficulties of evolution, if all such local conditions be removed as favoured the first localization of its products. We have no rule by which to measure the intensity of the constitutional cachexia, but after the disease has reached a certain point, there are signs which speak infallibly to the experienced eye—the pale and anxious countenance, with a slightly leaden hue; the pinched features, with slightly livid lips and nostrils, the constant hectic, increasing emaciation, frequent pulse, acrid and offensive discharge, and severe pains. All these speak a language not to be mistaken, and if to them be added nausea and weakness of digestion, a tickling cough, stitches in the side, a faltering pulse, cadaverous and anxious expression, we may safely predict a speedily fatal result.

Cancer of the uterus is, as a general rule, very slow in its development, and the symptoms of the incipient stage are not strongly marked, indeed, they are so slight as scarcely to call attention. Were the physician called at this period, he would probably find the muciparous glands in the interior of the cervix hard, and of the size of small shot, and somewhat painful on pressure; the os may be hard and fissured, and the cervix enlarged and indurated, and of a deep flesh colour, both within and externally. At this period we have found the whole uterus enlarged, and

having a more solid feel. At a still later period, a careful examination will disclose, probably, a knotted and indurated state of the vagina, and the mucous membrane thickened where it is attached to the cervix; the uterus may be more fixed, as if consolidated with the neighbouring organs; and there may be softening, abrasion, or commencing ulceration. But a long time may elapse before the disease has reached this stage. If the female be married, she will have for some time previously complained of pain in sexual intercourse, followed, perhaps, by a discharge of blood, while she labours under irritability of bladder, uneasiness in the central pelvic region, and a failure of general health. The *prophylactic* treatment of cancer uteri is the same as for all other chronic affections—attention to all those hygienic measures which tend to invigorate the general health. ASHLEIGH, however, recommends rest in a recumbent posture as absolutely indispensable to a cure; but it is evident there are many cases where the enforcement of such a rule would be very inexpedient, as it would tend to impair digestion, lessen secretory and excretory action, and increase general irritability.

The diet should be very simple and unstimulating; for the most part, milk and vegetables. MACILWAIN (*"The General Nature and Treatment of Tumours,"* 8vo. London, 1845) thinks the diminution of carbon, in the interdiction of grease, sugar, and alcohol, very important. The same writer recommends *aperients* combined with *narcotics*, as blue-pill and colocynth, with opium or henbane. Dr. MONTGOMERY recommends an *alterative course of mercury* in the early stage.\* Our countryman, Professor DEWEES, recommends the occasional abstraction of a few ounces of blood, especially if the catamenia have ceased; and if there is severe throbbing pain just above the sacrum, he enjoins losing six or eight ounces of blood by cups or leeches. *Purging*, Dr. D. thinks, is never to be omitted; "for there is no one remedy," he remarks, "that is of such decided efficacy in this disease." The salines are preferable, as *sulph. mag., tart. pot. and soda, sup. tart. pot., phosph. soda, &c.*; or equal parts of *sulphur and magnesia, or crem. tartar and sul-*

*phur, or rhubarb and aloes, castor oil, or magnesia.* The use of purging in this affection, according to Dr. D., is to solicit large serous discharges from the intestines, with a view to relieve the engorged state of the pelvic viscera, and at the same time not to weaken the system too much by its excess. Care must also be taken not to cause mucous discharges, and to observe closely the effects produced. Great attention, too, according to Professor DEWEES, is to be paid to *diet*, the blandest food, as milk and vegetables, only to be allowed, as bread, rice, Indian or rye mush, or unbolted wheat-flour mush; the fruits of the season; tapioca, oatmeal gruel, sago, arrow-root, &c. "The influence of this course of diet," says Dr. D., "is much more efficient than we might at first be willing to admit; but the fact is unquestionable, that it almost immediately relieves pain after it has been adopted." All kinds of alcoholic drinks are to be forbidden, as well as spices and other condiments. Great care is to be observed in regard to *cleanliness*; the acid and offensive discharges are to be regularly removed by injections of tepid water, flax-seed tea, or the hip-bath; and *carbonic acid gas, lime, pyroligneous acid, or chloride of lime or soda*, are to be employed for the correction of the fetor by their chemical effects. The use of carbonic acid gas, which has been recently recommended as a new remedy for the relief of neuralgia and other painful affections of the uterus, was introduced by Dr. DEWEES in the same cases, and especially for carcinomatous affections of this organ. "We have enabled several patients," he remarks, "to derive much comfort, as well as temporary relief, from the extrication of this gas within the cavity of the vagina, by means of a flexible tube of a sufficient length and size, attached to the mouth of a bottle, in which there is mixed diluted sulphuric acid and the carbonate of lime. This may be introduced into the vagina several times in the twenty-four hours. In two or three instances this substance has relieved the severity of pain whenever it was employed, as well as diminished the offensiveness of the discharge." (*"A Treatise on the Diseases of Females,"* 8vo. Phil., 1833, p. 264.) Dr. D. also regards *rest*, i. e., a horizontal position, without intervening exercise, as a sine qua non in the cure of this disease. The pain is to be relieved by "morphia or denarcotized laudanum;" and when rejected by the stomach, it must be given by enema. If vegetable food disagrees, or is not sufficiently nutritive, it is to be exchanged for animal, and the gastric acids are to be neutralized by the alkalies. Sometimes the sulphuric or nitro-muriatic acid fulfils this indication best. We refer to the work above mentioned for the details of the treatment advised by Dr. D., as we are satisfied that little, if any, improvement has been made upon it since.

[Dr. MACKENZIE (*London Lancet*, 1856) has published an able paper, in which he traces uterine to *hepatic disease*, in three ways: 1st, through the medium of the direct sympathy subsisting between the uterus and liver; 2d, through the derangement of the assimilative processes which invariably results from chronic hepatic disturbance; and 3d, through the debility of the nervous system which sooner or later inevitably follows upon long-continued derangement of any important organ of the body. To the first of this series of causes he attributes many uterine affections of a variable and casual character, such as *hystericalgia, leucorrhœa, and menstrual irregularity*; to the second, many functional and structural lesions of the uterus, of a more fixed and persistent character, such as congestive and inflammatory conditions, indurations, hypertrophies, fibrous growths, certain forms of *leucorrhœa*, and *rheumatic hysteria*, to which cancer might be added; to the third, a predisposition to uterine disease generally, the precise character and nature of which would vary with the nature of the exciting and other occasional causes. The treatment of these cases, admitting this pathology to be correct, he says, should be conducted with reference to three indications: 1st, to restore the tone and functional activity of the liver by the persevering employment of small, under-militating doses of mercury, keeping strictly within the tonic and stimulating range of the remedy; 2d, to improve the assimilative functions generally by careful attention to dietetic and hygienic measures, together with various therapeutical means; 3d, to restore the tone and vigour of the nervous system, which has been impaired by the long continuance of hepatic derangement. These views are well worthy of consideration.]

In the early stages of cancer uteri, we think we have observed good effects from the topical use of *iodine* to the cervix by the speculum, in the form of the compound ointment, as follows: *R Iodine, 3ss.; iodide of potassium, ʒj.; alcohol, ʒj.; lard, ʒij.* The friction should be persevered in for several minutes; or the *comp. tinct. of iodine* may be applied by means of a sponge. By the persevering use of this means such indurations have, in several instances, been entirely removed. The *nitrate of silver*, in the form of the saturated solution, will be preferable to the iodine in cases

where the lining membrane of the os, or around its margin, is tender and red, or where the same parts are softened or ulcerated, or where ulceration is dreaded, or the discharges are copious and fetid. It not only changes the unhealthy condition of the parts, but affords marked relief to the pain. If the case be beyond the reach of art, life may be prolonged and comparative comfort afforded by the frequent employment of these local applications, in connexion with anodyne and demulcent injections, and the proper regulation of hygienic means. We have in some instances seen the best effects from a pill of rhubarb, iron, and quinine; and in two cases, FOWLER'S solution of arsenic seemed to arrest the disease. It is better, however, to treat the disease on general principles than to trust to any supposed specifics. It must, however, be acknowledged that, as yet, cancer of the uterus must be ranked among the *opprobria medicorum*.

*Excision of the neck of the uterus* has been repeatedly practised, both in this country and Europe, for cancer of this organ; and Dr SIMPSON is an advocate for the operation under the following circumstances: 1st, great morbid hypertrophy, by elongation of the vaginal portion of the cervix uteri; 2d, corroding ulcer, when limited to the lips of the cervix, and pathologically identical with the form of lupus or malignant ulcer, so well known on the face; 3d, circumscribed and local forms of carcinomatous disease, or excrescence of the lips and lower segment of the cervix uteri. Few, however, will coincide in the opinion that simple hypertrophy of the cervix either justifies or requires so severe an operation, and the generally insidious and irregular progress of corroding ulcer seldom renders it amenable to operative treatment. We would rather say that excision of the cervix should be confined to cases of epithelial cancer, in which we know that a removal of the entire diseased part often effects a permanent cure; for it is of these that M. PAGER remarks that, "among all the cancers, they present the general or constitutional features of malignant disease in the least intense form. They commence at the latest average period of life; they appear to be most dependent on local conditions; they are least prone to multiplication in internal organs and they are associated with the least evident diathesis or cachexia." In one case, Dr SIMPSON has operated successfully, conception having taken place within ten days after the operation. The conclusions of ASHWELL are doubtless correct, viz., 1st, that the operation is an easy one; 2d, that excessive and dangerous bleeding is not a necessary accompaniment; 3d, that in some instances, for the time over which subsequent observation has extended, cancerous ulceration of the cervix uteri has been cured by it. The dangers are, hæmorrhage, uterine or peritoneal inflammation, malignant ulceration of the excised surface, or of any portion of the diseased structure which may have been left behind. We can scarcely conceive of any circumstances which would justify the extirpation of the entire uterus for a cancerous affection of the organ.]

**BIBLIOG. AND REFER.**—The *Bibliography and References* which I have appended to this article are almost entirely modern; for it is only within a recent period that the diseases of the Uterus have been fully investigated. —*Schævus*, De Morbis Mulierum, lib. iv., cap. ii.—*J. - [AM. BIBLIOG. AND REFER.—There are but few monographs by American physicians on the subject of the Uterus and its diseases, but numerous essays and cases relating to this subject are scattered throughout our numerous medical journals. Were the facts which they contain properly collected and digested, they would form the basis of a very valuable work. The principal authors on this branch of medical science are DEWEES, MEIGS, MILLER, and BEDFORD. But the American practitioner has access, through the medium of reprints, to the best foreign works on Diseases of Females, such as ASHWELL, GOOCH, WEST, CHURCHILL, SIMPSON, TYLER SMITH, MONTGOMERY, COLOMBAT DE L'ISÈRE, BENNET, &c., &c., &c. The following are but a small portion of the references

which might easily be made to works or papers connected with the subject of this article.—*C. D. Meigs*, a Treat. on Acute and Chronic Diseases of the Neck of the Uterus, Svo, Phila.: also, Report on same subject, with col'd plates, in Trans. of Amer. Med. Assoc., vol. vi., p. 365, 1855; also, "Woman and her Diseases," "System of Midwifery," and Translat. of *Colombat de l'Isère* on Diseases of Females, &c., Svo, p. 719. Philad., 1845. (*One of the ablest Works extant on this subject; more than 1000 writers on the subject are quoted or referred to in its pages.*)—*Samuel Annin*, on a New Method of Relieving Persons affected with Prolapsus Uteri, in Am. Journ. of Medical Science, vol. xviii., p. 334.—*W. L. Sutton*, Two Cases of Inversion of the Uterus, in Ibid., vol. iv., N. S., p. 83.—*A. D. Chaloner*, Fibrous Tumour of the Uterus, in Ibid., vol. x., N. S., p. 75.—*J. E. Taylor*, on Rheumatism of the Uterus and Ovaries, in Ibid., vol. x., p. 45; also, Cases of Engorgement of the Uterus, Irritable Uterus, and Prolapsus, in N. Y. Journ. of Medicine, vol. iv., p. 70.—*J. C. Beales*, Remarks on Engorgement or Congestion of the Cervix Uteri, in Ibid., vol. iv., p. 10.—*Edward Rigby*, on the Constitutional Treatment of Female Diseases, 12mo, p. 255. Phil., 1857. Uterine affections of every kind are regarded by this author as secondary, not primary, idiopathic diseases, and requiring chiefly constitutional treatment, especially purgatives, inasmuch as torpid liver and constipated bowels are generally in fault. Leeches and caustic applications to the cervix are not, however, wholly proscribed, as "solid lunar caustic" in ulceration. In cancer uteri, sulphate of iron and iodide of arsenic are recommended. This writer also describes *Prolapsus of the Ovary*, it descending into the recto-vaginal pouch—a rare affection, we imagine.—*Charles West*, an Inquiry into the Pathological Importance of Ulceration of the Os Uteri, Am. ed., Svo. Phil., 1857.—*W. P. Dewees*, a Treat. on Diseases of Females, 10th ed., Svo, p. 632, with plates. Phil., 1857.—*Fleetwood Churchill*, on the Diseases of Women, &c., Amer. ed., by *D. Francis Condie*, Svo, p. 684. Philad., 1857.—*Samuel Ashwell*, a Pract. Treatise on Diseases peculiar to Women, 3d Am. ed., Svo, p. 500. Phil., 1857.—*Henry Bennet*, a Pract. Treatise on Inflammation of the Uterus, its Cervix, and Appendages, and on its connexion with Uterine Disease, 4th Am. ed., Svo, p. 450, with wood-cuts. Phil., 1857.—*J. B. Brown*, on some Diseases of Women admitting of Surgical Treatment, with cuts, Am. ed., Svo. Philad., 1857.—*J. Leconte*, on Carcinoma, in New York Lancet, p. 284, 299.—*J. B. Strachan*, Case of successful Excision of the Cervix Uteri in a Scirrhus State, in Am. Journal of Medical Science, vol. v., p. 307.—*Edward John Tilt*, Dis. of Menstruation and Ovarian Inflammation in connexion with Sterility, Pelvic Tumours, and Affections of the Womb, Svo, N. York, 1855.—*Gunning S. Bedford*, The Diseases of Women and Children, 4th ed., Svo, p. 692. N. Y., 1857.—*H. V. Wooten*, a Case of Prolapsus Uteri permanently cured by Excision of the Vaginal Fold, with Remarks, in South. Med. and Surg. Journ., Augusta, vol. i., p. 310.—*G. G. Smith*, a Case of Uterine Hydatids, in Ibid., vol. i., p. 253.—*J. M. B. Harden*, Case of Prolapsus Uteri during Labour, in which artificial means were necessary to effect delivery, &c., in Ibid., vol. i., p. 248.—*J. Painchaud*, a Remarkable Uterine Tumour, in Bost. Med. and Surg. Journ., vol. xix., p. 265.—*James McKeen*, Case of Retroversion of the Uterus, in Ibid., vol. xii., p. 261.—*J. C. Warren*, Extirpation of half the Body of the Uterus and a portion of the Vagina for Cancer, in Ibid., 1829.—*J. B. Toby*, Case of Prolapsus Uteri, in Am. Journ. of Med. Science, vol. iv., p. 532.—*B. Smart*, Case of Inverted Uterus, in Ibid., vol. xvi., p. 81.—*W. L. Atlee*, Case of successful Extirpation of a Fibrous Tumour of the Uterus by the large Peritoneal Section, in Ibid., N. S., vol. ix.—*E. Fisher*, Inversion of Uterus, in Illinois Med. and Surg. Journ., Dec., 1845.—*D. P. Condie*, Review of *J. H. Bennet* on Dis. of Uterus, in Am. Journal of Med. Science, vol. ii., N. S., 1846.—*W. P. Buel*, Report of Dis. of Females, treated at New York Dispensary, in Ibid., vol. vii., N. S., p. 96.—*T. J. Garden*, Polypus of Uterus expelled by Ergot, in Ibid., vol. vii., p. 363.—*E. Warren*, Inflammation of the Uterus, in Bost. Med. and Surg. Journ., vol. xxxiii., 1845.—*T. Chadbourne*, Polypos and Malignant Tumours, in Ibid., vol. xxxii.—*L. Perkins*, Uterine Tumour, in Ibid., vol. xxxii., p. 370.—*S. Sargent*, on Operation for Uterine Tumour, in Ibid.—*D. Gilbert*, Removal of Uterine Tumour, in Bost. Medical and Surgical Journ., vol. xxxi., p. 249.—*J. Pancoast*, Successful Removal of a large Fibrous Tumour from the Uterus, in Ibid., vol. xxxi., p. 189.—*Jas. Deane*, Polypus in Utero, in Bost. Med. and Surg. Journ., vol. xxx., p. 449.—*J. F. Gray*, on Prolapsus Uteri with reference to the Modus Operandi of Dr. Hull's Utero-Abdominal Supporter, in Trans. of Med. Soc., State of New York, vol. iv., p. 31.—*J. Chapman*, Retroversion of Uterus relieved by Percussion, in Maryland Med. and Surg. Journ., 1842.—*Drs. Hermann and Werneburg*, Case of Extirpation of Uterus for Cancer, in Bost. Med. and Surg. Journ., vol. xxvii.,

p. 307.—*C. Waller*, Treatment of Cancer of the Womb, in Ibid., vol. xxiii., p. 10.—*D. V. Folts*, Osteo-Sarcomatous and Fibrous Tumours of the Uterus, in Ibid., vol. xxii., p. 325. (*A very interesting Case of true Osteo-Sarcomatous Tumour of the Uterus.*)—*B. Carpenter*, Cases of Uterine Inflammation, in Ibid., vol. xvii., p. 233.—*Jos. Warrington*, Translation of *Dupuyroux* on Diseases of the Uterus, with Notes, Svo, p. 455. Philadelphia, 1837. (*An excellent Work.*)—*J. Ward*, Congenital Retroversion of the Uterus, in Boston Med. and Surg. Journ., vol. xviii., p. 270.—*M. Hibbard*, Case of Uterine Tumour removed by Operation, in Boston Med. and Surg. Journ., vol. viii., p. 68.—*Jos. Condoek*, Case of Inverted Uterus, in Ibid., vol. viii., p. 245. (*Caused by pulling on the Cord; no restoration took place, but regular Menstruation occurred afterward.*)—*J. Cotton*, Case of Cartilaginous Cervix Uteri, requiring an Operation to accomplish Delivery, in Ibid., vol. iii., p. 23.—*J. F. Peblee*, on Displacements of the Non-gravid Uterus, their Local and Constitutional Effects, and their best modes of Treatment, Fiske Fund Prize Dissertation, in Am. Journ. of Med. Sciences, July, 1853. (*A very comprehensive and valuable Essay.*)—*O. C. Gibbs*, on Polypus Uteri, in Am. Medical Monthly, April, 1854.—*W. C. Roberts*, on the Isolated Tumour of the Uterus, commonest on the posterior wall, in N. Y. Journal of Med., vol. iii., p. 190.—*C. R. Gilman*, on some Diseases of the Os Uteri, and the mode of investigating them, in Ibid., vol. iii., p. 181; also, Case of Corroding Ulcer of the Uterus, with complete Destruction of all the Internal Organs of Generation, in Am. Journ. of Med. Sciences, vol. ii., N. S., 1841.—*J. V. P. Quackenbush*, Case of Removal of Uterine Polypus, in Ibid., vol. ii., p. 13.—*W. H. Han-litt*, Case of Hydatids of the Uterus, in Ibid., vol. ix., p. 49.—*A. R. Davis*, an Essay on the Nature and Curability of Heterologous Tumours, in Ibid., vol. x., p. 382.—*John H. Griscom*, a Case of Abstraction of the Uterus after Delivery, in N. York Journ. of Med., vol. i., p. 74.—*John A. Srett*, an Essay on Cancer of the Uterus, in Ibid., vol. i., p. 34. (*A very valuable Contribution to the Pathology of this subject.*)—*A. C. Post*, Case of Retroflexion of the Uterus, in Trans. of the Am. Med. Trans., vol. ii., 1849, p. 253.—*B. W. McCready*, Case of Retroflexion of the Uterus, in Ibid., p. 155.—*Washington L. Atlee*, Prize Essay, The Surgical Treatment of certain Fibrous Tumours of the Uterus heretofore considered beyond the resources of Art, in Trans. of Am. Med. Assoc., vol. vi., p. 547, 1853.—*J. K. Mitchell*, Case of Racciferous Hydatids of the Uterus, in Med. Exam., vol. i., p. 73, 1845.—*E. A. Haycock*, The History of a Retroverted Uterus, in Com. of Mass. Med. Soc., vol. i., p. 13.—*George O'good*, a Remarkable Uterine Case, in Med. Com. of Mass. Med. Soc., vol. i., p. 30.—*William Moore*, Uterine Hydatids, in N. Y. Med. and Phys. Journ., vol. i., p. 151, 1822.—*J. C. Hat h*, Case of Inverted Uterus, in Boston Medical and Surgical Journal, vol. xl., p. 277.]

**VACCINATION.**—**SYNON.**—*Vaccinia* (from Vacca, a cow), *Variola vaccina*; *Variole vaccina*; *Vaccine*, vaccination, Fr. *Kuhpocken*, *Schutzblattern*, Germ. *Vaccina*, *Vaccinazione*, Ital. *Vaccine*, *Cow-pox*

**CLASSIF.**—III. CLASS, III. ORDER (Author in Preface, &c.)

1. **DEFIN.**—*Variola vaccina*—a vesicular disease developed in the human subject by inoculation of cow-pox, or of the lymph from the variolous vesicles affecting the cow

2. **I. HISTORY OF.**—It would appear from ancient Sanscrit writings, that vaccine inoculation had been practised in India from the earliest ages, and that the preservative influence of vaccination was known, and had recourse to, in different parts of the East. Mr BRUCE, Consul at Bushire, states that vaccination was well known in Persia for many ages. HUMBOLDT found among the inhabitants of the Cordilleras of the Andes the belief that the eruption on the udder of the cow preserved them from small-pox. These indications of the practice of vaccinations were, however, unknown at the time when EDWARD JENNER, a general practitioner in Berkeley, observed the protective influence of the vaccine disease from the natural and inoculated small-pox, and when he submitted this influence to the tests of experiment and practical observation. In 1775

Dr. JENNER remarked, that a number of persons in Gloucestershire could not be inoculated with small-pox; and, having become aware that there was a popular belief that persons who had caught the cow-pox, from milking the cows, were not subject to small-pox, he was induced to investigate the grounds for this belief. In the course of his researches, and after encountering numerous difficulties and opposing opinions, which would have discouraged all but those who possessed a determined will and powerful genius, he found that the cow was subject to a variety of eruptions on the teats, all of which had received indiscriminately the name of cow-pox. He learned to distinguish between these, and ascertained that one only was possessed of a specific protective power over the human body. This he called the *true* cow-pox, the others the *spurious*. He next ascertained that the true cow-pox underwent progressive changes; and that it was only at one period of its progress, or in the acme of eruption, when it was endowed with specific or preventive, or anti-variola properties. During the investigation of this branch of the subject, Dr. JENNER was struck with the brilliant idea that it might be practicable to propagate the disease by inoculation, first from the cow, and successively from one human being to another. It was not, however, until 1796 that he was enabled to take the decisive step of inoculating for the cow-pox, upon the success of which his grand scheme mainly rested. An opportunity of testing his ideas by satisfactory experiments was not afforded him until that year, when cow-pock matter in an active state was found, and parents were met with possessing sufficient confidence to submit their children to the important trial. On the 14th of May, 1796, James Phipps was vaccinated with matter taken from the hands of Sarah Nelmes. He passed through the disorder in a satisfactory manner, and was tested by variolous inoculation on the first of July following. The small-pox inoculation took no effect. JENNER now prepared to communicate the result of his long investigations concerning cow-pox, but delayed his work in the hope of furnishing additional proofs of the success of vaccination. These he was enabled to procure; and in June, 1798, he published, in London, his original essay, entitled, "An Enquiry into the Causes and Effects of the Variolæ Vaccinæ; a Disease discovered in some of the Western Counties of England, particularly Gloucestershire, and known by the name of the Cow-pox." This work deserves a particular notice. In it Dr. JENNER states his belief that this disorder does not originate in the cow, but is communicated to this animal from the horse, where it appears on the heels, and is known by the name of the *grease*; the hands of farm-servants and milkers being the medium of communication. He next suggests that the small-pox itself may have been originally morbid matter of the same kind, which circumstances had changed and aggravated into a contagious and malignant form. He afterward states his conviction that cow-pox inoculation leaves the constitution forever after secure from the infection of small-pox; and he concludes by enumerating four classes of persons to whom cow-pox inoculation holds out the prospect of great benefit: 1st. Those who, from family predisposition, may be presumed likely to take small-pox unfavourably; 2d. Persons of a scrofulous diathesis; 3d. Those who, from idiosyncrasy,

resist small-pox inoculation in early life; and, 4th. Those who are labouring under chronic forms of disease, in which counter-irritation is desirable.\*

3. At the end of July, Mr. CLINE made the first experiment with cow-pox in London, which succeeded perfectly; and soon afterward recourse was had to vaccination in many places. In his second publication, dated April, 1799, Dr. JENNER judiciously recommended calmness and mod-

[\* Some vaccine virus was forwarded by GLO. PEABSON, of London, to Dr. DAVID HOSACK, of New York, in the year 1797; but the discovery was not announced in the United States till 1799, in the Medical Repository of New York. In July, 1800, Dr. B. WATERHOUSE, of Cambridge, Massachusetts, first successfully practised vaccination in this country on four of his own children. Dr. VALENTINE SEAMAN was conspicuously active in introducing the practice into the city of New York. He obtained the virus from Dr. WATERHOUSE, and with it vaccinated his own son and many others. From this time forward the practice became general.

An act was passed in Massachusetts, in 1810, providing that "it shall be the duty of every town to choose persons to superintend the inoculation of the inhabitants with the cow-pox." This law was repealed in 1836, and the Revised Statutes provide "that each town may make provision for the inoculation of the inhabitants." This change, as Mr. SNATTUCK states ("Report of the Sanitary Commission of Massachusetts," Boston, 1850, p. 180), leaving it optional with the towns to do or not to do it, has probably caused the loss of many lives. Under the operation of the old law, many towns were accustomed, once in five or more years, to have a general vaccination of the inhabitants; but this custom, it is stated, has been generally discontinued, and the inhabitants are left liable to the disease from every fresh exposure. The same remark will apply to most of the States, and even large cities that have independent boards of health. Boston has provided that no child shall be admitted into the public schools without a certificate from some physician that it has been vaccinated. It also, as well as New York and most of our cities, provided for the gratuitous vaccination of the poor; but the means provided are very inadequate to the end proposed. It is not yet safe exactly to presume on the intelligence of the lower classes in our large cities; and as long as this is the case, compulsory measures will be necessary. Not only cities, but all towns and villages, however scattered the population, should have local boards of health, acting under a general State law, empowered, among other things, to provide for and enforce, if necessary, a general vaccination of the inhabitants as often, at least, as once in five years.

Strange, indeed, it is, that no police or sanitary regulations exist regarding the spread of small-pox in many, if not all our large cities. In New York city, a small-pox hospital has been provided on Blackwell's Island for the poor who may be attacked with small-pox; but removal thither is not made compulsory, nor are the sick from this disease placed under any quarantine whatever. So in Boston. Since the laws relating to small-pox in Massachusetts were repealed in 1837, no more restraint has been laid upon persons sick with this than any other disease, and the consequence is, it is rarely, if ever, absent from the large cities. During more than 40 years prior to 1837, the disease caused but 37 deaths in Boston only, and most of these were at Rainsford's Island; very few cases ever occurred in the city. But during the 12 years ending Dec. 31, 1849, since the repeal, it caused the deaths of 533 persons; and in the first six months of 1850, 146 died with it. There can be no doubt whatever that the prevalence of this disease in our large cities might be nearly, if not altogether, prevented. They should be divided into small districts, a health-warden appointed for each, who is a medical man, whose duty it should be to visit every family, whether invited or not, and to vaccinate or revaccinate every person, if necessary or expedient. By this plan the disease would soon disappear. If a case of small-pox should occur, means should be taken for its isolation, or removal to a small-pox hospital, or to a safe position out of the city. The 600 lives which are annually lost in New York city by this disease might in this way be saved, as well as the expense imposed on the city for the support of small-pox widows and orphans. In the present state of our knowledge on this subject, it is safe to say that every State, city, or town, which does not interpose its legal authority to exterminate the disease, incurs the responsibility of permitting the destruction of the lives and health of its citizens.]

eration in researches into the efficacy of cow-pox inoculation; but in 1800 he expressed his conviction that the cow-pox is capable of extirpating small-pox from the earth; and in his fourth publication, May, 1801, he again expressed the same sanguine opinion. The commencement of this century was remarkable for the progress of vaccination. In 1801 upward of six thousand persons had been vaccinated, and the greater part had been tested with small-pox. In 1800, 1801, and 1802, vaccination was introduced into France, Germany, Italy, Spain, and the East Indies. In 1802, Parliament voted Dr. JENNER a reward of £10,000 for the discovery, and in 1807, the additional sum of £20,000; and in 1808 vaccination was taken under the protection of Government.

4. In 1809, Mr. BROWN, of Musselburgh, published the opinion that the prophylactic virtue of cow-pox diminished as the time from vaccination increased. In 1818 and '19, an epidemic small-pox pervaded Scotland, and many vaccinated persons passed through a mild form of variola. The term "modified small-pox" was now adopted. Dr. MONRO, in 1818, published a volume on "*the different kinds of small-pox, and especially on that which sometimes follows vaccination*;" and in 1820, "*An Account of the Varioloid Epidemic*" was published by Mr. THOMSON, of Edinburgh. Between this date and 1823, when I wrote on the subject, as well as subsequently to the latter year, some very remarkable cases came before me in both public and private practice, occurring in the same and in different families, proving the impairment of the protective influence of vaccination with the growth of the body, and the lapse of time, until it entirely ceased, at least in many cases, after puberty, when vaccination was performed in infancy.

5. In 1825 the Bills of Mortality announced 1300 deaths by small-pox, among whom were several persons who had been vaccinated. Small-pox was epidemic in France in 1826 and '27, and in the northern parts of Italy in 1829; and in consequence of the numbers of the vaccinated who had been attacked by small-pox more or less modified or unmodified, the practice of revaccination commenced in Prussia and the German States, and was subsequently encouraged by their governments. This practice has more recently been voluntarily adopted by many in this country.

In 1833-4, small-pox prevailed epidemically in Ceylon, when a considerable number of the vaccinated died; and it made great devastations in Hindostan on several occasions, both prior and subsequent to this date, and many of the vaccinated have been carried off by it. Dr. GREGORY states that the admissions into the Small-Pox Hospital, in 1838, more than doubled the average number received annually, prior to the discovery of vaccination, and that two fifths of the admissions consisted of persons who had been vaccinated. Many had the disease severely, and more than twenty of the number died. Recently Parliament has legislated on vaccination and small-pox, but in a way which is neither satisfactory to our profession nor beneficial to the community.

6. Having now stated, from the history and certain of the results of vaccination, what has been urged against it, and having, when treating of small-pox and variolous inoculation, noticed what appeared in favour of the latter (*see* SMALL-POX, § 104-114), it now becomes a duty to ad-

vert to the evidence which opposes what has been advanced both at this place and in that referred to. The facts evincing the failure of vaccination in many cases, and of the impairment of the protective influence of it with the growth of the body, and with the course of time, are here stated, with no disfavour to the practice of vaccination, but with a due regard to what appeared to be the truth as respects the results of this practice. When treating of variolous inoculation, I took occasion to compare the results of it with vaccination more especially as observed in Eastern and inter-tropical countries. Much of the difference and of the difficulty in this matter must be attributed to imperfect, careless, or abortive vaccination, and to the influence of small-pox, when prevailing as a severe or malignant epidemic, on persons thus imperfectly protected.

7. Among the more recent evidence in favour of the protective influence of vaccination, there is none which seems to deserve more attention than that which has been furnished by Dr. BALFOUR. His deductions have been founded on the returns of the Army, the Navy, and the Royal Military Asylum. But although these appear very favourable, they are actually not so much so as a mere glance at the tables he has given might evince; for he adds up the aggregate numbers of the several years to which he refers, and places these numbers opposite to the number of cases of small-pox. It should be premised that soldiers are all protected by vaccination, or by small-pox. Thus, from the returns forwarded annually to the Army Medical Board, during eight years, from the 1st of April, 1844, to the 31st of March, 1851, inclusive, he constructs the following table of cases of, and deaths from, small-pox, out of the aggregate strength, or rather the strength multiplied by the years:

Among troops serving in	Aggregate strength.	Cases of Small-pox.	Deaths by Small-pox.	Annual ratio per 100 of strength	
				Cases	Deaths.
The United Kingdom.....	251,537	557	56	2.188	.220
Temperate Colonies.....	557,112	160	29	.287	.052
Tropical Colonies.....	314,131	28	8	.083	.025
Total.....	1,125,840	745	93	.662	.083

8. This table is, however, fallacious, as the aggregate here given is not the actual number of different individuals, for the much larger proportion, if not the great majority, of the average number of troops in these eight years (140,730), are actually the same individuals enumerated again and again, or even for several years, unless the discharges and deaths have been remarkably great; while the number of cases and of deaths are the total amount furnished during the eight years from among the individuals actually serving; for it cannot be shown that during these eight years the army was formed of 1,125,840 different persons.

9. The fallacy now pointed out exists in the other tables, more especially in that giving the results as respects the Navy, and from it no correct inference can be drawn. His Report, however, of vaccination of the boys of the Royal Military Asylum is a much more important document, and this I adduce. "Of 5774 boys taken on the strength of the establishment from its opening in August, 1803, to the 31st of December last

(1851), 1950 are recorded as having marks of small-pox, 3636 marks of vaccination, and 188 no satisfactory mark of either. The last having been all vaccinated on admission, there were 1950 protected by previous small-pox, and 3824 by vaccination."

	Number over whom observa- tion extend.	Of whom subsequently		Ratio per 1000.	
		Had Small-pox.	Died of Small-pox.	Cases.	Deaths.
Boys with marks of small-pox.....	1950	12	4	6.15	2.05
Boys with marks of vaccination.....	3824	27	..	7.06	0.00

It must be presumed that the boys leave the asylum when they reach puberty or manhood, or before this latter epoch. The results subsequently are not known, and cannot well be ascertained; and let it be remembered, that the liability to small-pox, modified or otherwise, then becomes greatest. Nor should it be overlooked that exposure to the infection of small-pox cannot be as great in garrisons and in an asylum as in the general community. Besides, when a case of small-pox occurs in either garrisons or in an asylum, it is removed to the infirmary, or other places of seclusion; whereas among the public, with few exceptions, a case, whenever it occurs, becomes a focus of infection, from which the disease spreads in all directions among the unprotected.\*

10. There can be no doubt that vaccination, satisfactorily performed, with recent lymph of a proper description—the vesicles having regularly matured, without hindrance or accident, and with a sufficient number of punctures—is a most valuable protection from small-pox; and if this protection be not afforded during the whole life of the individual vaccinated, in some cases; it at least, in all, is a protection for many years, the variolous disease, when caught subsequently, notwithstanding this protection, being, with few exceptions, a comparatively mild disease—these exceptions, especially when they are fatal, still admitting of doubts as to the proper performance of vaccination, and as to the efficacy of the lymph or matter employed. It cannot, however, be denied that the protection from small-pox furnished by vaccination to persons who have been vaccinated in infancy, and have grown up, is not so fully manifested when small-pox is epidemic, as at other times; nor does it appear to be as com-

plete when vaccinated persons migrate to warm climates, and are there exposed to small-pox infection, as when they remain in temperate countries; but this requires farther inquiry.\*

11. II. OF THE COW-POX IN THE COW.—This disease is not of frequent occurrence. It appears as an epidemic, and rarely or never unless where cattle are collected together in herds. It then breaks out at irregular periods, and from causes unknown. Dr. JENNER's experiments concerning it were often interrupted by its complete disappearance. Dr. JENNER at first considered that cow-pox in the cow was generally a local disorder confined to the udder; and such it has appeared to be in some, if not in many instances. Subsequent observations, however, have shown that it is really a febrile constitutional disease, accompanied with eruption, although the febrile symptoms are often not very manifest. True cow-pox shows itself on the nipple of the cow, in the form of irregular pustules, or more strictly as vesicles passing into a pustular state. At their first appearance they are commonly of a pale-blue colour, or rather of a hue approaching to livid, and surrounded by an erythematous or crysipelatous inflammation. They sometimes degenerate into phagedenic ulcers. The animal appears indisposed, and the secretion of milk is much lessened. The cow is subject to other pustular sores on the nipples, which are of the nature of common inflammatory sores, and possess no specific quality. They do not present any bluish or livid tint, or any crysipelatous redness around them. They desiccate quickly, and create no apparent constitutional disorder in the animal. Such a complaint is frequent among cows in the spring, when the calf is suckling. It was called by Dr. JENNER the spurious cow-pox.

12. *Casual cow-pox in man* is caught by milkers of affected cows, and appears on the hands and wrists in the form of inflamed spots, which go on to suppuration, forming pustules of a circular form, having elevated edges and depressed centres, and are of a colour inclining to blue. After a time absorption takes place, and swellings appear in the axilla. Fever succeeds with headache, sometimes with vomiting, and in some cases with delirium. The febrile symptoms decline in three or four days; but the sores on the hands often remain, very painful and difficult to heal for a considerable time. No eruption on the skin follows the decline of the febrile symptoms.

13. III. INOCULATED COW-POX.—i. *Regular Cow-pox*.—When vaccination has been successfully performed on a healthy child, the puncture may be felt slightly elevated on the second day; and on the third, and even on the second, a slight efflorescence may be distinctly seen, by the aid of the microscope, surrounding the inflamed

\* The above admissions cover about the whole ground claimed by the strongest advocates for vaccination. During a dispensary practice of several years among the poor of New York city, where 500 deaths annually occur from small-pox, I rarely met the disease among those unprotected by vaccination, while it was very common among others; and where it did occur among the former, it was rarely, if ever, attended with any danger. I might also appeal to my own personal experience to prove that the influence of the vaccine disease is not wholly lost at puberty; for having been vaccinated in early childhood, I took the varioloid at the age of 26, from attending a small-pox patient, and had the disease in its very mildest form, not more than half a dozen pustules appearing, and the constitutional symptoms very light. As our author concedes that the vaccine disease "is a protection for many years;" and as all concede that it protects till about the age of puberty, and that vaccination at that period restores to the constitution that exemption from small-pox which it previously enjoyed, while we have a powerful argument in favour of revaccination, we lose none of our admiration and appreciation of that great discovery, whose unspeakable value and importance time and experience only tend to confirm and establish.]

[\* In the 26th volume of the *American Journal of Medical Sciences* I have described an epidemic varioloid disease, which occurred in the town of Gorham, New York, which, from the great variety in the character of the eruptions, gave rise to a warm and angry controversy among the neighbouring practitioners, some contending that the disease was small-pox, others that it was vari-cella. A majority of those attacked had been vaccinated in early infancy, and, in general, the disease assumed a milder form in proportion to the recency of the vaccination. The eruption, in different cases, had all the specific characters of *variella*, *varioloid*, *confuent* and *distinct* small-pox, *pemphigus*, *purpura*, *crisipel* s, and even other forms of cutaneous disease. (See additions to art. "Small-pox," p. 898.)]

point. On the fifth day a distinct vesicle is formed, having an elevated edge and a depressed centre. On the eighth day it appears distended, with a clear lymph. The vesicle on this, its day of greatest perfection, is circular, and either pearl-coloured or slightly yellow. In its form and structure it resembles the pustule of small-pox. Its margin is turgid, firm, shining and wheel-shaped. It is composed of a number of cells, by the walls and floors of which the specific matter of the disease is secreted. On the evening of the eighth day, an inflamed ring begins to form around the base of the vesicle, which continues to increase during the two following days. This areola, or ring, is circular, its diameter extending from one to three inches. When at its height, on the tenth day, there is considerable hardness and swelling of the subjacent cellular tissue. On the eleventh day the areola begins to subside, leaving, as it fades, two or three concentric circles of a bluish tint. The vesicle has previously burst, and its surface acquired a brown colour. The lymph which remains becomes opaque and gradually concretes; so that about the end of the second week the vesicle is converted into a hard, round scab, of a reddish-brown colour. This scab contracts, dries, blackens, and about the twenty-first day falls off, leaving a cicatrix, which is permanent in after life, is circular, somewhat depressed, striated, and indented with six, eight, or ten minute pits, corresponding to the number of cells of which the vesicle has been composed.

14. Slight constitutional disturbance is observed about the seventh or eighth day, or sometimes a little earlier. The child is hot, restless, or feverish, and the bowels slightly disordered; but this subsides in two or three days. A few children, however, present no sign of constitutional disorder, which is not by any means essential to the success of the vaccine process. About the tenth day a papulous eruption, of a lichenous character, sometimes appears on the extremities, occasionally extending to the trunk of the body. It continues for about a week, or even lasts after the scab has fallen off. This vaccine lichen is met with chiefly in children of a full habit, where numerous vesicles had been raised on the arm, which discharge freely. It is an accidental occurrence, which, like the constitutional irritation, indicates a full effect of vaccination on the system; neither the one nor the other, however, being deemed requisite to ensure such effect.

15. In adults, vaccination exhibits the same succession of phenomena as in infants. The vesicles, however, are thinner and more easily ruptured. The lymph is usually of a yellowish tinge, and the areola is more extensive. The glands of the axilla frequently swell, which is rarely observed in children; and constitutional irritation is more frequent and greater. Secondary lichen is less frequent and less marked. Dr. HEM, of Ludwigsburg, considers that the adult lymph is more energetic than infantile lymph, but this requires farther investigation.

16. ii. *The irregular or anomalous Vaccine Vesicle.*—The above normal course of the vaccine vesicle is liable to be disturbed in various ways, and by various causes. Imperfect vaccination presents no uniform sign, but exhibits different appearances in different cases, such as pustules, ulcerations, scabs, and irregular vesicles. The

*irregular vesicle* is attended at its commencement by urgent itching; provoking scratching or rubbing, to which the subsequent appearances are unjustly attributed. The vesicle throws out a premature efflorescence, and advances too rapidly; so that on the fifth day it has attained its height, when it will be found raised on a hard inflamed base. "It is acuminate, or conoidal, and gives the appearance of a common festering sore produced by a thorn." It is generally of a straw colour, and contains some opaque matter or pus, instead of a clear transparent lymph. The scab produced by it is small, of an amber colour, and drops off by the tenth day.

[We believe that too little attention is paid to these irregularities and anomalies. Where the vesicle has been broken, so that the characteristic marks of the disease are wanting, where the local inflammation is very severe and results in the formation of pus, where there is a papular eruption over the body of the child, where, especially the operation is followed immediately, or, in a day or two, by a pustule, without a previous vesicle, irregular in shape, yellow in colour, acuminate, easily broken, and terminating in a soft, yellowish, ragged-looking crust, falling off on the fifth, sixth, or seventh day, no confidence should be placed in the genuineness of the disease, and revaccination should be performed at an early period. Too much caution cannot be observed in this regard. We believe that the spurious forms of cow-pox are by no means uncommon in this country, and that to this cause must chiefly be attributed the loss of confidence in this prophylactic, and the still-lurking preference of some for inoculation over vaccination. These irregular forms, it is true, are very common in cases of revaccination; but this only proves that the influence of the former vaccination is still experienced, and that the system is still protected from small-pox. There are *two kinds* of spurious vesicles; the *first* bears a strong resemblance to the true in many respects; its edges are commonly elevated, its contents nearly limpid, and it continues the usual time; but it commences with a creeping scab of a pale-brown or amber colour, making a long, slow progress, sometimes unattended by any efflorescence; the vesicle is more transparent, and the pellicle is generally thinner and easily torn. The *second kind* appears early and increases rapidly; is elevated in the centre, and globular, with more or less the appearance of a common phlegmon, and when punctured, there issues opaque fluid, resembling what is produced in any other festering sore. It is more easily ruptured; at the sixth or seventh day, it generally runs into a perfectly purulent state. The areola is irregular or notched, resembling a large blotch; has a fiery or livid aspect; is not shaded off into the surrounding skin; seems rather to be under than upon its surface, while, at the same time, it is less extensive, nor is the hardness around it so evident; a ragged scab prematurely covers the vesicle, or, when the black crust should form, a yellowish sore appears, drying and breaking out again, with an oozing from under it.

Imperfect vesicles are, in general, smaller and more globular than the true kine-pock; they have not the turgid, convex margin, but a somewhat punctured base appearing to slope off into the surrounding skin; they have not a cellular structure; the contents are not a clear transparent

lymph, but a straw-coloured, opaque, or purulent fluid; the areola not defined, nor of so vivid a rose tint, but ragged and diffuse, appearing about the seventh or eighth day, or earlier; on the fifth or sixth, of a dark red colour, with less hardness than the true areola, and disappearing sooner; the succeeding crust is smaller, of a light-brown or amber colour, irregular and friable, forms earlier, separates sooner, and leaves an indistinct and not pitted cicatrix.\*]

17. The causes of this abortive or irregular vesicle are not well ascertained. Sometimes the bad quality of the lymph employed may occasion the irregular vesicle, three or four children, or more, vaccinated from the same source, exhibiting the same irregular appearances. Dr. GREGORY supposed that it might arise from the influence of weather or season, as he observed it in many more cases on the approach of winter than in the spring or summer. Some believe that this irregularity arises from the use of lymph taken at too late a period of the disease. But although lymph taken after the tenth day will often fail to reproduce vaccinia, yet when it does succeed, the vesicle goes regularly through its course, and is perfectly effective in preserving from small-pox. Besides, the scabs of cow-pox, moistened with a little lukewarm water, will often produce the disease in all its purity.

18. Irregularity of the vaccine vesicle is sometimes attributable to a bad habit of body. "The proof is, that one child only out of many vaccinated with the same lymph, shall show the anomalous form of cow-pox. It is a singular but very important fact, that an imperfect vesicle, the offspring of a perfect one, degenerated by some peculiarity of habit in the individual vaccinated, shall sometimes reappear in all its original purity and perfection, when transplanted into a healthy, well-disposed subject."

19. In some instances the specific inflammation, or areola, is very severe, extends from the shoulder to the elbow, or even invades the trunk, requiring recourse to cold lotions, active purgatives, and febrifuges. The vesicle, instead of scabbing in the natural way, is converted into an ulcer, discharging freely. The inflammation thus arising is, however, only temporary; and, if it have commenced at its proper period, it does not appear to weaken, or in any degree to interfere with the protective virtue of the vaccination. The vesicle about the fifth or sixth day occasionally becomes sealy; a species of psoriasis taking the place of the areola. In a few other cases true erysipelas supervenes. These anomalies deprive the cow-pox operation of all claim to protective influence. A much more frequent and successful anomaly is retarded cow-pox; the advance of the vesicle being without any apparent cause suspended. The areola does not form before the tenth or twelfth, but ultimately the process is completed, the success of the vaccination being in no degree prejudiced.

20. iii. *Complications of Cow-pox.*—A child is sometimes vaccinated after having been infected by *measles* or *scarlatina*, and before their respective eruptions have appeared. In such cases the cow-pox is generally retarded. In a case recorded by Dr. GREGORY, it was retarded sixteen days while the measles ran their course. Genuine *chicken-pox* (*varicella lymphatica*) will run its course along with cow-pox, without interfering

with any of its phenomena. The modifications which cow-pox undergoes when *small-pox* invades the system about the same time, are interesting. When vaccination is performed during the incubative stage of casual small-pox, this latter being yet latent, the vaccine vesicle either does not advance, or advances tardily and imperfectly. Sometimes, however, cow-pox and casual small-pox may be seen running their full course in the same person at the same time. In no case, however, does the cow-pox so inserted modify the course of the small-pox. When the variolous and vaccine fluids are inoculated on the same day each disease occasionally proceeds, preserving its original character. In some cases, however, they mutually restrain and modify each other. The vaccine vesicle in these is smaller than usual and irregular in its progress, while the variolous pustules which follow are of the kind termed *variola verrucosa*, or commonly swine-pock, stone-pock, or horn-pock (see *art. CHICKEN-POX*, § 2, *et seq.*); are hard and shining, surrounded by little inflammation, and suppurate imperfectly; the little matter they contain being absorbed, leaving the cuticle hard and elevated for some days afterward. The eruption on the extremities does not pustulate, but is papulous, minute, and terminates by desquamation. Although the eruption be modified in most cases, there is generally considerable disturbance of the constitution under the joint influence of the variolous and vaccine poisons.

21. When vaccination precedes variolous inoculation by a period not exceeding four days, both diseases advance locally. "Sometimes an eruption of small-pox papule follows. At other times the variolous fever is slight, and unaccompanied by eruption. Under these circumstances, matter taken from the primary vesicles shall sometimes communicate cow-pock and small-pox respectively; but more commonly the variolous poison predominates, and contaminates the lymph of the vaccine vesicle." Variolous inoculation at any period not exceeding a week from the date of vaccination will take effect and be followed by a pustule: after that time no effect is produced. Dr. WOODVILLE on several occasions inoculated with a mixture of variolous and vaccine matter. The result was not to be depended upon, but in general pure small-pox succeeded. When small-pox inoculation precedes by three or four days the insertion of vaccine lymph, the vaccination advances, but after the tenth day the fluid in the vaccine vesicle becomes purulent, and in that state will communicate small-pox. Those who have undergone variolous inoculation in early life are generally unsusceptible of cow-pox. Vaccination, however, in such circumstances produces a certain degree of effect, the disorder manifesting itself in an imperfect and modified form. The fluid in the resulting vesicles cannot be trusted to for producing the genuine cow-pox.

22. iv. *Recurrent Cow-pox.*—When cow-pox has completed its regular course, the constitution is left, for a very considerable time at least, unsusceptible of the same disorder. But this law does not obtain if the revaccination is performed at very short or at very distant intervals: (a) At a very *short interval*, or on the fourth, fifth, or sixth day after a regular primary vaccination, the vesicles of the second vaccination are accelerated in their course, so as to overtake the first crop, and the whole mature and scab together. The

\* See Labatt on Cow-pox, p. 90.

second crop of vesicles, however, is not more than one fourth the normal size, and the areola is equally contracted. Mr. BRYCE (*On Cow-pox*, Edin., 1802) ingeniously availed himself of this circumstance, and, by testing by revaccination on the fifth day, he endeavoured to ascertain the full influence and actual security of vaccination. The plan, well known as BRYCE's *test*, has been extensively adopted. To obtain this test in greatest perfection, he advises the revaccination to be performed at the end of the fifth or beginning of the sixth day; and if no acceleration of the second crop of vesicles be observed, it is to be concluded that no constitutional effect has resulted from the first vaccination. The second is then to be regarded as the primary affection, which, in its turn, is to be tested by a third vaccination, and so on until we are satisfied that the constitutional effect has been fully produced. Dr. GREGORY adds, that "some persons have claimed for this suggestion the highest honour, and have even considered Dr. JENNER's discovery as incomplete without it. Dr. JENNER, however, never laid much stress upon it. In doubtful cases it is a prudent practice, but it has been extolled far beyond its real merits. It shows whether or not constitutional influence has been exerted by the primary vesicle, but it does not determine what has been the degree of such influence—in other words, it does not show whether the constitutional effect has been *complete* or otherwise."

23. (b) Revaccination at *distant intervals* from the date of primary vaccination, is deserving of notice. Dr. JENNER, in his original essays, stated that the human body, after a time, had the susceptibility of cow-pox renewed. Dr. GREGORY describes four different effects of revaccination at distant intervals: 1st. In many cases, especially if the interval from the primary to the secondary vaccination has not exceeded five years, the skin appears completely insensible to the vaccine matter; 2d. At intervals exceeding ten years, the virus irritates locally. In three, or at farthest four days from insertion, an areola of irregular shape appears around a minute, itching, acuminated, and angry vesicle. The glands of the axilla frequently swell; and in particular habits of body, especially in adult females, irritative fever is superinduced. A scab forms on the eighth day, which soon falls off, leaving no permanent cicatrix; 3d. In other cases, a vesicle forms more gradually, without either local or constitutional irritation; a slight areola succeeds, and the vesicle yields, on the seventh day, a considerable quantity of thin lymph; but this lymph is incapable of propagating the disease; 4th. In this set of cases, the second vaccination runs a perfectly regular course. A circular areola forms on the eighth day, and the lymph propagates a genuine cow-pox.

24. IV. NATURE OF VACCINIA.—*The Identity of Vaccine and Variolous Disease.*—When Dr. JENNER announced vaccination as an antidote to small-pox, he was strongly impressed with the idea of the common origin of human and epizootic maladies; and, conformably with this idea, he viewed small-pox as the most remarkable malady which equally affects man and the higher animals; and that this malady, in its less malignant forms, assumes the form of cow-pox, chicken-pox, and swine-pox. This, however, had been long a vulgar opinion, and is somewhat analogous to the view I stated when treating of scarlet

fever, which, I remarked, had appeared within the last three hundred years, and was derived from a similar disease in the horse. JENNER believed not only that small-pox and cow-pox were essentially the same disease, but that the former was a malignant variety of the latter, the parental malady being the cow-pox. This opinion was expressed by the term *variola vaccina*, the name he gave cow-pox, when first introduced to the notice of the scientific community. The researches of Mr. CEELY have more recently confirmed the intimate connexion Dr. JENNER contended for between cow-pox and small-pox; inasmuch as he has shown that the inoculation of the cow with variolous matter produces in that animal the true vaccine or cow-pox; and that inoculation of the human subject with the vaccine matter thus generated in the cow from variolous inoculation propagates genuine cow-pox in man. He has farther adduced some facts, which, however, require farther investigation, but which appear to prove the origin of the cow-pox, or vaccinia, in the infection of the cow by small-pox when occurring epidemically or sporadically in human subjects. Among other observations, Mr. CEELY states that he went to examine some cows affected with cow-pox; and that their proprietor, Mr. POLLARD, "at the same time, expressed his conviction that *his cows had been infected from human small-pox effluvia*, to which he considered they had been exposed."

25. The above facts, although scanty as they are, go to prove the following: 1st. That cow-pox originates in small-pox infection or contagion caught by the cow; 2d. That the infection of the cow by small-pox gives rise to vaccinia—an eruption which resembles the pustule of small-pox, but which cannot communicate small-pox, although it propagates itself as true vaccinia; 3d. That, unlike, or differing from, variola or small-pox, vaccinia is not communicated, at least from the cow to man, or from one human subject to another, by an effluvium or emanation proceeding from the affected at any stage of its course; 4th. That, like variolous inoculation, vaccination is capable, when properly conducted, of protecting from small-pox, with few exceptions, and at least for a considerable time; 5th. That the amount of evidence favours the opinion that vaccinia is a modification of variola, the modification proceeding from the virus of the latter having infected the cow, and occasioned the vaccine eruption; 6th. That the amount of evidence also favours the inference that vaccination protects, at least in many instances, from small-pox only for an indefinite time, and that the length of that time is indeterminate or indeterminable; 7th. That the duration of the protection may depend upon climate and various unascertained circumstances, and that there is reason to infer that, in such cases and circumstances where the protection fails after several or many years, the impairment of the protective influence is gradual, and progressive with the duration of time.

26. From the foregoing it will be seen that, while I believe, with Dr. JENNER, in the intimate connexion of variola with vaccinia, and with chicken-pox and swine-pox, yet we have no proof that variola has sprung from cow-pox; the evidence being in favour rather of cow-pox, and the other kinds of pox being varieties or species of small-pox, arising out of the passage of this latter malady through the higher of the lower animals—more conclusively of the passage of the variolous

morbid poison through the cow, as respects vaccinia.

27. Such appears to be the relation subsisting between cow-pox in the human subject and in the cow and small-pox; it may next be inquired what connexion exists between *vaccinia in the cow* and the *grease in horses*. Dr. JENNER believed that they were both identical, and that cow-pox never occurs in dairy districts, except where there is access to horses; he thereby denied the spontaneous origin of the disease in the cow. Later observations have, however, proved not only the identity of cow-pox and grease, but have shown, at the same time, first, that cow-pox does originate in the cow without access to horses; and, secondly, that cow-pox is communicable to man from the horse without the intervention of the cow, and with nearly equal facility as from the cow itself. Dr. GREGORY states that this branch of the theory of vaccination has been investigated with great diligence by Dr. LOV, of Whitby, Dr. SACCO, of Milan, and Dr. DE CARRO, of Vienna. The last-named author states, "that the matter in use at Vienna from 1799 to 1825 was partly British vaccine, and partly originated from the grease of a horse at Milan without the intervention of the cow. The effect was so similar in every respect that they were soon mixed; that is to say, that after several generations, and in the hands of innumerable practitioners, it was impossible to distinguish what was vaccine, and what was equine." "The whole British settlements," he adds, "were *equinated*; for the first liquid drop sent thither was the second generation of Milanese equine, or greasy matter, transplanted at Vienna." It cannot be inferred that the grease in horses was the origin of variola; and there is as little evidence of the grease having caused vaccinia in the cow, as there is of the latter having produced the former. It is, therefore, by no means improbable that both vaccinia and grease, being capable of communicating and propagating an identical affection, viz., that commonly called cow-pox, to human subjects in endless succession, are variola modified in its manifestations and properties by its passage through these two species of animals. The grease of horses, being proved, or admitted, conformably with the above evidence, to communicate and propagate an affection in every respect identical with vaccinia, the same inferences which I have deduced respecting this latter, apply also to it, if, indeed, this branch of the subject of vaccination be not viewed as still requiring farther investigation, more especially as respects the protective influence of the affection propagated from the grease in horses.

[If the researches of Dr. GEORGE GREGORY ("Med. Chir. Trans.," vol. iv., N. S.) are to be relied on, the morbid secretions of the cow, which possess the power of protecting the human system against the assaults of small-pox, may be produced in that animal in *four different modes*. 1st They are generated spontaneously in the cow, under certain circumstances of soil, season, and locality, and are often met with in cows soon after parturition, in the spring season, and when feeding upon young grass; but they arise also spontaneously from other and less known causes, and the disorder spreads like other epizootic maladies. It was this form of vaccine disease JENNER chiefly studied.

2d. The very same malady, developing the very

same morbid secretion, is often observed to spread *by contagion*, that is, by the application of the diseased secretion, thus generated, to the teats of healthy cows, differently circumstanced, by the hands of the milker.

3d. The same morbid secretion, possessed of the same qualities, is often generated in the teats of the cow by the application to them of the matter formed by the heel of the horse, when affected with the disorder called "*the grease*." This *greasy matter* may also be transplanted to man directly, without the intervention of the cow, proving that the anti-variola property does not depend on any peculiar change which the virus undergoes in passing through that animal.

4th. The same morbid secretion may be excited artificially in the cow by applying to the teats, or the mucous surfaces of the vagina, vaccine lymph from the arm of a child, even though twenty years had elapsed since that lymph had been humanized or assimilated to the human constitution.

5th. To these four modes of exciting a morbid secretion in the cow, called *vaccinia*, Mr. CERLY has added a *fifth*, by showing that the same object may be attained by applying to the mucous surfaces of the cow the matter of human small-pox. The vessels of the part are excited to the production of a fluid or humour, identical in all its properties with that which arises from a constitutional and febrile disturbance of the cow's system from contagion, from the matter of *grease*, or the long-humanized vaccine virus.

Dr. GREGORY supposes that other modes of exciting this morbid secretion in the cow exist, which may yet be discovered. and that we are not justified in concluding that the last mode mentioned is the most important, or as affording the true clue to the mystery of vaccine protection. This writer also contends that, as *vaccinia* is non-contagious, and febrile disturbance is not essential to its perfect development, the *vaccine* is probably a poison *sui generis*, and its relation to variola still hypothetical; that the real and intimate nature of the protection it affords is still unknown to us; and that a thorough knowledge of its anti-variola powers must be derived not from analogy, but from an extended and careful observation of facts, continued through a long series of years.]

28. V. PROTECTIVE INFLUENCE OF COW-POX.—This subject has occasioned much discussion during the last quarter of a century, and more especially during the last few years; and the amount of protection which cow-pox affords against small-pox has been often entertained, but as yet by no means satisfactorily ascertained.—a. There are various circumstances which render it most difficult to determine this question; for the idiosyncrasy of some individuals seems to oppose infection by the vaccine virus, either for a time or through life; and, if such an insusceptibility of the disease be admitted, it may be farther inferred that in others, the insusceptibility being less, the vaccine infection may be incomplete, and the protection afforded be proportionately imperfect. It may be conceded that, where the disposition in the constitution to receive the vaccine infection is either wanting or incomplete, the protection must be equally deficient; and hence, to estimate the protective influence of vaccination, it must be considered that the process has not been duly completed, and that no protective influence can be claimed from it, unless the vaccine vesicles and the local phenomena proceed regularly, and leave

a cicatrix, as described above. But, independently of the indisposition of the constitution to receive the vaccine disease, or of the disposition to receive it imperfectly, the health of the individual, and the state of the season or weather, may render vaccine infection either abortive or incomplete. It has been proved that attempts to vaccinate have often failed in hot countries, and in the warm localities of temperate climates, during hot and dry states of the atmosphere; and a similar temporary insusceptibility to small-pox inoculation, during the same state of atmosphere, has been observed. The impaired health of a person also may render him insusceptible of vaccination, until his health is restored; and various unascertained circumstances may have the same effect, either permanently or for a time. It may be inferred, all things being considered, that, where an insusceptibility to vaccination exists, an equal indisposition to small-pox may be expected; but, as a rule, there may be many exceptions to this, and it would be unwise to confide in it.

29. *b.* Besides circumstances more immediately connected with the individual, there are others depending upon the virus itself. The vaccine lymph may be deteriorated by long-keeping, or by a warm and humid, or a very warm and dry atmosphere, if it be even for a short time exposed to these states of the air. It may also be either inert, or imperfect in its operation and constitutional as well as local effects, owing to its having been taken from the vaccine vesicles at a too early, or a too late stage of the process of maturation, as already noticed (§ 17); or even to its having been too long kept, or to its insufficient protection from the action of the atmosphere. The manner in which the inoculation of cow-pox is performed—or the efficient or imperfect operation of inoculation—may in some way also affect the results. The number of the incisions or punctures, and the actual deposit of the virus within the sphere of the action of the absorbents or veins, may not merely produce either a full and satisfactory effect, or no effect at all, but also an imperfect or an insufficiently protective effect.

30. *c.* *Imperfect vaccination* has been referred to a variety of causes. It has been very generally supposed that the vaccine virus becomes deteriorated by its passage through numerous human bodies, or that the protective influence is weakened by the length of time, and the long succession of subjects through whom it has been perpetuated, from its direct inoculation from the cow. Of this, however, there appears to be insufficient proof. It has been remarked, that persons who have been vaccinated by Dr. JENNER himself, before deterioration could possibly have commenced, have nevertheless been attacked by small-pox in after-life. A recent writer remarks, that, "so far from believing in any deterioration of virus from successive inoculation, there is reason to believe that, by a careful selection of well-predisposed children, the pock may even be restored from an imperfect to a perfect state, and by proper care, therefore, may be retained indefinitely in that condition. If children are successively vaccinated from each other, all of whom are from various causes ill disposed to take on the perfect disease, the virus may unquestionably degenerate, and at length wear out altogether. In tropical countries, and in confined localities, such an occurrence certainly takes place, but this is very different from

the notion of a virus deteriorated by the mere influence of time."

31. *d.* *Imperfect vaccination*, as a cause of failure of protection from small-pox, was much insisted on by Dr. JENNER. Vaccination is said to be imperfect when any considerable deviation from the ordinary course of the vaccine vesicles takes place. The deviations from perfect vaccination are imputed to one or more of the following causes: 1st. To spurious matter, or matter taken from the arm at an improper period of the process; 2d. To an insufficient number of vaccine vesicles; 3d. To preoccupation of the skin by some disease, in which a fluid is exuded capable of conversion into a scab, such as tetter, scald-head, ringworm, erysipelas, &c.; 4th. To robbing the vesicle incautiously of its contents, particularly when one only has come to maturity; 5th. External violence done to the vesicle, as rubbing or scratching it, especially during its early stages. That causes may, and often do, interfere with the success of the vaccine process, cannot be doubted; but the influence imputed to them cannot be determined; for it has been proved, by very few instances, it should be admitted, that vaccination, which, according to all indications, should have been considered perfect, has afforded only imperfect or only temporary security; while, on the other hand, cases in which one or other of the above causes has interrupted the regular process, have notwithstanding afforded perfect security. The instances in which single vesicles have preserved from small-pox, both casually and by inoculation, Dr. GREGORY states to be so numerous that no reliance can be placed on the notion which would connect the security of the individual with the number of maturing vesicles. A case of small-pox after vaccination will sometimes occur in a member of a family, all of whom have been vaccinated in the same manner, by the same practitioner, and having similar marks on the arm, and equally exposed to contagion, that one alone having become infected. It should also be recollected that vaccination under the same circumstances, especially of the members of the same family, may, upon exposure to small-pox infection, be followed by this malady, in its various grades of modification, according to the time that has elapsed from vaccination. It has even been ascertained that persons have caught small-pox after having been subjected to BRUCE's test of the perfect constitutional affection of the original vaccination. It should, however, be recollected that these are merely exceptions to the general rule of protection; and as exceptions have attracted greater attention than those which prove the rule.

32. *c.* *The presumed decadence of vaccine influence and protection* has been believed by many from an early period of the history of vaccination. Dr. JENNER, in his third publication, in 1800, remarked that there were some "who suppose that the security from small-pox, obtained through cow-pox, will be of a temporary nature only. This supposition is refuted not only by analogy with the habits of diseases of a similar nature, but by incontrovertible facts, which appear in great numbers against it." That analogy may be considered opposed to this supposition may be allowed, although the analogy is neither very close nor very conclusive; but the facts opposed to it were certainly neither strong nor very manifest, inasmuch as time, the necessary element of

their manifestation, had not then elapsed. That Dr. JENNER was, however, convinced, or at least most sanguine in this matter, is shown in his petition to Parliament, where he states that his discovery had the "beneficial effect of rendering, *through life*, the person inoculated with it perfectly secure from the infection of small-pox." He rested his arguments as to the permanency of the protection of vaccination upon his belief, which subsequent researches have proved to be well founded, in the identity of vaccinia and variola; but, even granting the identity, a very marked modification of the former from the latter, by the passage of the poison through the body of the cow, must be admitted, the result being a conversion of a frequently malignant and generally severe malady, into a mild disorder. Are we, therefore, from the mere admission of identity thus modified, to infer protection by means of the milder form of disorder? May it not be as justly inferred, that whatever protection is actually afforded by the milder form of the disease may possibly be sometimes overcome by the contagion of the more severe malady? and that the protection of the former, being weaker or milder than that furnished by the latter, may not be so endurable, especially in some constitutions and circumstances, and more particularly if the process of vaccination has not been perfect or complete in all respects.\*

33. It was admitted by Dr. JENNER, Dr. WILKINSON, and others, who believed in the permanency of vaccine protection, that, when the vaccine process has been *imperfectly* gone through, and when, from some peculiarity of constitution, the system receives only a portion of, or is insufficiently imbued with, that protective influence which cow-pox is capable of imparting, then "small-pox would recur, and thus the degree in which its phenomena were modified was proportioned to the degree of perfection which the vaccine vesicle assumed during its development."†

34. This partial protection from small-pox, admitted in the circumstances just stated, has, however, been extended by many to the more perfect processes of vaccination; and there are many medical men and others who believe that the protection is complete only for seven, or ten, or fourteen, or twenty-one years; but that the small-pox caught after vaccination is modified in proportion to the shortness of the time which has elapsed from vaccination; and that, after the longest of these periods, little or no modification is observed. This opinion has manifestly been pushed too far; for it cannot be correctly inferred that these facts,

which have undoubtedly been often observed, especially in certain families and persons, in whom peculiarity of constitution, irregularities or imperfections in the vaccine process and other circumstances, tending to account for the imperfect or non-permanent protection, by any means prove that such imperfect protection exists in all cases, or even in a very large minority of cases. The circumstances which secure the desired protection, or which weaken it, or even destroy it altogether, are as yet not known with sufficient precision, and are such as admit of very different opinions, being undetermined on this very important matter. It need only be inferred that the vaccine process should be studied, so as to secure its perfection as far as possible, and in this state that it should be generally practised with the belief that, although not an undoubted, or an universal, or always a permanent protection from small-pox, it nevertheless proves a permanent protection in the great majority of instances, and that, where the protection fails, it renders in the vast majority the small-pox a comparatively mild disease.

35. It has been attempted to calculate the proportion of the vaccinated who take small-pox. On this topic it is impossible to arrive at any approximation to the true result. The degree of severity of a small-pox epidemic, occurring in a community containing many vaccinated persons, may be expected to influence the result. Dr. CROSSE, in his account of the variolous epidemic of Norwich, in 1819, stated "that of the vaccinated, not more than one in twenty will be in any way affected by the most intimate exposure to small-pox contagion; and less than one in fifty will have the disease in a form answering to the generally received descriptions of modified small-pox." These calculations may have been justified by the epidemic in 1819; but they cannot be viewed as applicable to other circumstances, and more especially to later periods in the history of vaccination and of small-pox prevalence. This is one of the many instances in which statistics cannot be confided in when applied to disease.

[Owing to the large number of unvaccinated immigrants into the city of New-York, and perhaps other causes, the number of deaths from small-pox in this city has been for several years gradually on the increase. The following are the number of fatal cases of this disease for the corresponding years, taken from the city inspector's reports:

Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.
1804 16	813	2	1822	00	1831 224	1839 68	1847 53		
1805 6	184	2	1813 18	1832 8	1840 252	1848 544			
1806 48	18 5	94	1824 394	1833 25	1841 200	1849 326			
1807 59	1816	97	18 5	40	1834 233	1842 181	1850 231		
1808 6	1817	14	1826 58	1835 358	1843 117	1851 562			
1809 66	18 8	1	18 7	149	1836 173	1844 21	1852 47		
1810 4	1819	00	18 8	93	1837 164	1845 425	1853 636		
1811 117	1820	00	18 9	16	1838 91	1846 146	1854		
1812 21	1821	00	1830 176						

Perhaps this increase in the number of deaths by small-pox out of proportion to the increase of population may be owing more to some general epidemic or atmospheric, or other cause, than the failure in the protective powers of vaccinia, inasmuch as we find also a great and corresponding increase in the number of deaths from scarlet fever in the same city, as follows:

\* For this reason, laws against inoculation exist in most of the New England and Middle States, and ought to exist in all.]

† When we consider the numerous causes which modify the kine-pock, and may cause a failure in the vaccinating process, we shall not be surprised at the frequent occurrence of small-pox, or varioloid, among the vaccinated. Among the causes which modify the protective powers of vaccinia, Dr. GREGORY enumerates *puberty, change of climate, a severe attack of fever, and an epidemic constitution of the season*. Among the former may be reckoned, as most common, the employment of virus before it has undergone sufficient elaboration, the absence of constitutional affection from rupture of the vesicle, and certain individual idiosyncrasies. There is no reason whatever for supposing that vaccine virus deteriorates by passing through numerous human bodies; for the vaccine vesicle of JENNER is the true vaccine vesicle of to-day, and the distinctive signs by which its incubation and progress are marked are the same now as they were then.]

Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.	Year.	No. of Deaths.

36. VI. SMALL-POX AFTER VACCINATION.—I have adverted to this topic when treating of SMALL-POX (§ 38), but I may make a few remarks respecting it which were then omitted. Variola, as it occurs after vaccination, is generally a mild disease. The pustules are usually small, hard, and tuberculated, few of them maturing perfectly. Yet the small quantity of matter they do contain commonly produces small-pox in others; and the exhalation from the affected also communicates the disease.\* This modified state of variola is not usually followed by pits or scars. Cases of much greater severity do, however, occur, and even assume the worst of confluent forms, or terminate fatally, as I have observed on several occasions. In some instances, a fatal termination may be imputed to the accompanying or secondary fever of small-pox attacking a delicate or scrofulous frame—or persons advanced in life, of a plethoric habit, or affected by some visceral disease—or those predisposed to, or actually labouring under, pulmonary or other maladies. In such case the physician perceives the true source of the fatal result, while the friends of the patient impute the event to small-pox. Soon after vaccination was introduced, cases of failure were imputed to imperfections in the vaccine process in these cases; and not unfrequently the varioloid disease which followed was so slight as to induce doubts of its nature; and very probably there were sometimes grounds for entertaining the skepticism. But with the lapse of time, facts, proving the failure of the protective influence, became more numerous, and were observed most frequently among adults. Dr. GREGORY, who was for many years physician to the small-pox hospital, states that “very few children have been received into the hospital under such circumstances (after vaccination); and those few have invariably had a mild disease, more allied to chicken-pox

than to small-pox: whereas all the severe cases, and the greater proportion of the mild ones, have occurred in adults, in whom an interval varying from 10 to 30 years (the average eighteen) had elapsed since the date of vaccination.”

[Dr. STEWART (*Ed Med. and Surg Jour.*, 1840) maintains, 1st. That vaccination affords an imperfect protection from small-pox at all periods of life; 2d. That the protection becomes more imperfect as the individual advances in life; 3d. That at the age of puberty the influence of vaccination (provided it has been had recourse to in infancy) nearly ceases—at any rate, in the majority of cases, at the age of 20, vaccination, he thinks, ceases to exert any protective influence whatever. These conclusions, it is stated, are confirmed by Dr. GREGORY, of the London small-pox hospital, in a letter to the author.

The benefits, however, of vaccination in protecting against attacks of small-pox will be very manifest when we look at the record of orphan asylums, and other institutions for the receptancy of children, where the greatest care is bestowed on vaccination. In the orphan asylum of Charleston, S. C., which in 1829 contained 150 children, not a single case of small-pox or varioloid occurred during the prevalence of that disease, though no additional restriction was imposed upon their intercourse with the citizens. (*Am. Jour. Med. Sci.*, Nov, 1831)

Over one thousand children were received into the different orphan asylums of Philadelphia up to 1841, and of the whole one only died of small-pox, although 65 cases of the disease occurred. Ten of these had no cicatrix, including the one that died, and probably had never been vaccinated.

Of several thousand children received in the different orphan asylums of New York since their foundation, no deaths have occurred from small-pox, although the varioloid has broken out at different times, in a light form, in several of them. The same is true of the New York House of Refuge, which had received 2657 children up to the year 1845.

Baltimore presents the like return, out of 3500 children that have been inmates of the Almshouse and different orphan asylums of that city. Thus we have an aggregate of over 11,000 children under 14 in these different institutions, and but one death from small-pox. Thus 5856 children were received into the New York Almshouse, from Nov. 1st, 1834, to May 1st, 1843, and though the varioloid prevailed extensively in that institution during that period, there were but eight deaths from it among the whole number; total, 16,000 children vaccinated, 8 deaths. Compare this with the mortuary statistics of Glasgow in former times. From Sept., 1671, to April, 1672, there were 800 deaths from small-pox in that city, with a population of 13,000. At the present time, with a population of over 250,000, the cases of this disease which prove mortal do not amount annually to one sixteenth part of the number which then occurred in one third of the time, among a population about one twentieth as large as at present.

During the prevalence of a most malignant and fatal small-pox in Philadelphia, in 1827, but one well-ascertained death from that disease was discovered to have occurred among 80,000 vaccinated persons. According to Drs. MITCHELL and BELL (“*Report to Med. Soc. of Phil.*”), of 248 cases of variola and varioloid treated at the small-pox hospital of that city, 155 were unprotected, of

\* The late Dr. FORAY found a higher ratio of successful vaccinations among those who had previously had small-pox than among those who had been simply vaccinated. Thus, of those who had been vaccinated, there were 141 successful, and 364 unsuccessful cases; 55 imperfect. Of 74 who had had small-pox previously, 29 were successful vaccinations, and 45 failures. Of 52 who had not been vaccinated, 25 were successful, and 27 failures. Total, 686. Thus he found that the successful vaccinations among those who had had small-pox amounted to 1 in every 2.1, while in the revaccinations this ratio is only 1 in 4. So, also, Dr. JOHN DAVY (“*Malta Statistics*”) shows that, although the influence of vaccination in preventing small-pox was less than that of small-pox itself in preventing a second attack, yet of those attacked by small-pox after having been vaccinated, the mortality was only 4.2 per cent., while the cases of recurrent small-pox gave a mortality as high as 9.3 per cent. So, also, at the small-pox hospital of Philadelphia, in 1823, ‘24, Drs. MITCHELL and BELL report but a single death out of 64 vaccinated; 3 died out of 9 who had been inoculated with variola; 3 died out of 7 who had had small-pox before; and of 155 wholly unprotected, 85 died. So of 14,470 persons who were attacked with small-pox while it prevailed as an epidemic in France, in 1840, 1688 died; out of 24 cases of recurrent small-pox, 3 died; while out of 403 persons attacked subsequent to vaccination, but 6 cases proved fatal! proving that, while small-pox has a mortality among the unprotected of 1 in 8, the varioloid affection is generally mild, seldom destroying more than 1 in 100.]

whom 85 died; 64 were vaccinated, of whom only one died; 9 were inoculated, of whom 3 died; 7 who had had small-pox before, of whom 3 died; and of the 13 whose condition was unknown, none died.]

37. VII. OPERATIVE MEASURES.—*A. The performance of vaccination*, although a simple, is a nice operation, requiring much attention to several circumstances. Care should be taken to avoid a failure, as it often causes a delay, or a neglect of the repetition of the operation. Failures arise chiefly, 1st. From the selection of the lymph; 2d. From the mode of operating; and, 3d. From the constitution or state of health of the individual operated upon.—*a.* The vaccine lymph should be recent, if it can be obtained in this state. It should be perfectly clear and limpid, and the earlier it is taken from the vesicle the better. Lymph may be taken with every prospect of success after the fifth day, and up to the eighth and ninth days. That taken on the tenth day should not be confided in. When vesicles are too often or too roughly opened, on the seventh or eighth day, the serum of the blood may commingle with the lymph, and impair, or even altogether destroy, the efficacy of the latter. A vesicle should always be treated gently.—*b.* The lancet used in the operation ought to be clean and sharp. A vaccinating lancet should have a broad shoulder, as well as a sharp point, to enable it to retain an adequate portion of virus. The skin should be kept tense during the operation, and six or eight punctures be made at convenient distances from each other, and to a slight depth. Provided that a genuine lymph of due intensity comes in contact with the absorbing surface of the cutis vera, it matters not whether much or little blood flows from the punctures. The quantity of blood that escapes depends more upon the child's habit of body than on the operator. A plethoric child generally bleeds freely when vaccinated, but generally exhibits the most perfect appearances as to the effect.—*c.* The child operated upon should be in perfect health. Vaccination ought to be delayed during the existence of any disease—at the period of dentition—when the skin is affected by any eruption—or when the digestive canal is disordered—unless some pressing occasion should require it. The best age for vaccinating is between the third and fifth month after birth, before dentition has commenced.

38. *B. Preservation of Vaccine Lymph*—Fresh lymph should always be preferred when it can be obtained; but there is often no other resource than preserved lymph. Being liable to spontaneous decomposition, as well as to other changes too slight or delicate to admit of demonstration, unless in its effects after inoculation, and either impairing or destroying its efficiency, great difficulty has been experienced in preserving it, and more especially in transmitting it to tropical climates in an active state. Dr. C. GREGORY states the following to be modes of preserving lymph which are now adopted: 1. It may be preserved fluid for several days between two pieces of glass, about an inch square, which fit each other accurately. When dry, the lymph will often, if carefully moistened by the breath, propagate the disease. 2. Vaccine lymph may be preserved on ivory points, shaped like the teeth of a comb. These should be twice dipped in the fluid of the vesicle, and allowed to dry slowly. They should be retained, when used, in the wound or puncture

for about half a minute. They are considered very effectual. 3. The lymph may be kept in a fluid state in capillary tubes, having a bulb at one end. They admit of being hermetically sealed. But to prevent spontaneous decomposition the lymph should be collected in minute quantities only. 4. Mr. BRYCE, in 1802, stated that vaccine scabs may be used for communicating the disease, and it has been ascertained that this is the most certain mode of transmitting cow-pox to warm climates. When about to be used they ought to be rubbed to a powder, and moistened with a little tepid water. When thus reduced to the consistence of thin mucilage, they form an artificial lymph. Punctures should be numerous where the lymph is employed. 5. Dr. JENNER occasionally used dossils of lint, saturated with the fluid of an eighth-day vesicle. These he placed between glasses, one surface of which had a small central cavity; the glasses being tied together, their edges sealed, and the whole covered with sheet lead. Preserved in this manner vaccine lymph will retain its fluidity and efficiency for a considerable time.

39. VIII. REVACCINATION.—The phenomena presented by revaccination after comparatively short intervals have been noticed (§ 23). It, however, becomes necessary to take a brief survey of the practice of this measure after long intervals, with the view of affording a complete protection against small-pox. It having been believed by many medical men, and it having become the popular belief, in several countries, that vaccination, however completely performed, is weakened in its protective influence by the lapse of time, or growth of the frame, a recourse to revaccination has been had, in some countries to a great extent. Dr. GOLDSON, in 1804, first announced this doctrine, but assigned the remarkably short period of three or four years for the decadence of protection. In France, MM. CAILLOT, BOULU, BERLAN, GENOUL, and others both in this and in other countries, supported this opinion, but assigned much longer periods for this occurrence, the time assigned by them varying in the opinions of each from ten to twenty-four years, but they all agreed in believing that the loss of protective power was gradual and progressive. M. P. DUBOIS endeavoured, in 1825, to refute this doctrine as a general inference, although he admitted the facts upon which the opinions of these physicians were founded. The epidemic prevalence of small-pox soon afterward in France, Germany, and Denmark, confirmed, by the numbers of vaccinated attacked, the opinion that vaccination lost, after the lapse of a number of years, its powers of protection from that malady. From this period—about 1829—revaccination began to be practised on the Continent, and on great numbers in Germany, Sweden, Denmark, Prussia, and in France. In 1833, it was adopted in the Prussian army, and was performed on 48,047 persons, and was successful in 15,269. In 1834, 16,673 successful cases were obtained in 44,454 operations. In 1835, 15,315 were successful in 39,192 revaccinations. In 1836, in 42,124 revaccinations, 18,136 fully succeeded, and 9040 presented an irregular form of the eruption. Of 14,048 persons, in whom revaccination failed, 1569 were successful on the repetition of the operation for the second time. In 1839, 41,481 soldiers of the Prussian army were revaccinated; of this number, the cicatrices of the first vaccination were distinct in 33,225,

imperfectly distinct in 5889, and not detected in 2367. Revaccination succeeded in 19,249, and was imperfect in 5354. Similar results have been obtained from revaccination in several of the German states, in Hanover, &c., between the years 1835 and 1842. In France, revaccination has not been much practised, and in England still less.\* During the reign of Louis PHILIPPE, the Royal Academy of Medicine of Paris was consulted respecting the propriety of having recourse to revaccination. This body were opposed to this measure, as they believed that it would weaken confidence in vaccination. M. DEZEIMERIS protested against this decision, and was successively followed by MM. FIARD, HARDY, PRESSAT, and others, who published memoirs on the subject in the French journals. M. VILLARET, in 1843, practised revaccination in 401 soldiers of the 7th regiment of dragoons; it was successful in 307; and in 153, who had formerly had *small-pox*, the operation fully succeeded in 97. In a second series of 447 persons, who presented perfect vaccine cicatrices, 402 had cow-pox a second time; and of 123 persons marked by *small-pox*, 89 presented a successful vaccination. MM. BOSQUET, FIARD, GUERSANT, and BLACHE, who, in 1828, expressed their belief in the permanent security furnished by cow-pox inoculation, have subsequently altered their opinions, and have practised revaccination in numerous cases; and have strenuously advised this measure as the only certain means of preventing *small-pox*, by sustaining the prophylactic influence of vaccinia.

[Dr. WENDT, in Copenhagen, revaccinated 3964 persons, of which 2756 were successful, and 1208 failures. Dr. AGGEUS, of Silesia, revaccinated 962, of which 822 were successful, 72 failures, and 68 spurious or imperfect. The Vaccine Committee of France, in 1839, revaccinated 6652, of which 718 were successful, and 1283 spurious or non-successful. In 1840, the same committee found 270 successful out of 2214 cases of revaccination, 1717 failures, 227 spurious or imperfect. M. VILLENEUVE, the same year, found 223 successful out of 2199 cases of revaccination, and 1976 failures. The late Dr. FERRY, of New York, vaccinated 569 soldiers at Fort Wood, in 1840, of which 141 were successful, 364 failures, 55 spurious or imperfect. Dr. KIRKBRIDE, of Philadelphia, revaccinated 209 in 1840; 44 successful, 165 failures. We copy the following Tables from Dr. FERRY's "*Prize Essay on the Protective Powers of Vaccinia*" (*N. Y. Jour. Med.*, Sept., 1844).

These statistics contain the results of revaccination in the Prussian army, the Vaccine Committee of France, and all other known authentic sources,

[\* M. VILLENEUVE, chairman of the committee on vaccination of the Royal Academy of Medicine, Paris, after examining the reports of 41 departments of France in relation to vaccination and revaccination, deduced from them the following conclusions in 1840: The whole number vaccinated for the first time was 30,413; in 560 of these it was unsuccessful. The number of revaccinations was 2199; of these, 1976 were unsuccessful. Of those who had been already vaccinated, 365 had the varioloid, and 6 died. Thus it appears that the proportion of cases in which vaccination does not succeed is only one in 54½, while others who have investigated the subject place it as high as ¼ or 1-10. Of the 2199 revaccinations performed in persons of different ages and sexes, who had been successfully vaccinated at some previous time, 223 were successful. So the proportion of successful cases was as 1-13 or 1-14. In 365 cases of varioloid occurring after well-established vaccination, the proportion of deaths was only 1-45 or 1-46, while the sporadic *small-pox* kills 1 to 1-10; and when the disease is epidemic, 1, or even more, perish. (*Annales d'Hygiène*.)]

Year.	Number Vaccinated.	CICATRICES IN THOSE REVACCINATED.			
		Of these had perfect cicatrices.	Imperfect cicatrices.	No cicatrices.	Revaccination successful in
1834	44,454	33,634	7,134	3,686	18,156
1836	42,124	32,635	6,143	2,946	15,315

1841	13,523	13,523	2,54	15,777
Totals	72,704	61,746	9238	96,637

and it is believed that they afford conclusive evidence of the necessity and importance of revaccination, under all possible circumstances. It is worthy of note that, prior to the order for revaccination in the Prussian army, it was not unusual for the different barracks to be a prey to varioloid disease; but now the whole army, notwithstanding its repeated exposure to similar causes productive of the disease, enjoys an almost entire immunity.]

40. In 1845 the Academy of Sciences of Paris published a Report, containing the following conclusions: 1. The protective influence of vaccination is complete as regards the great majority of the vaccinated, and temporary as respects a small number only; and in these latter it is almost absolute up to the period of puberty. 2. *Small-pox* rarely attacks the vaccinated before the age of ten or twelve; and it is from this age to thirty or thirty-five that they are chiefly exposed. 3. That in addition to its preservative influence, vaccination endows the constitution with an influence which renders the symptoms of *small-pox* much milder and of shorter duration. 4. Cow-pox, directly or recently derived from the cow, is attended by a much more intense local phenomenon, and by a more certain and permanent effect than that which has passed through a great number of human subjects, this intensity of local action subsiding after many successive vaccinations. 5. The preservative influence of vaccination appears not to be intimately connected with the intensity of its local effects; nevertheless, in order to preserve the properties of vaccinia unimpaired, it is prudent to renew it as frequently as possible from the cow. 6. Revaccination is the only means we possess of distinguishing the complete success of vaccinia from the less complete grades of protection. 7. Revaccination, however, is not certain evidence that the vaccinated in whom it had succeeded would have been destined to contract *small-pox*, but merely that it was probably among those that this latter malady was most likely to appear, if they became exposed to its infection. In ordinary times revaccination may be practised after fourteen years; during epidemic *small-pox* it may be practised after a shorter period.

41. It would appear from the circumstance of so many persons having presented the regular vaccinia after *small-pox* (§ 39), as stated above, that the complete development of the local action after revaccination cannot justly be viewed as a certain proof that the successfully vaccinated could have been infected with *small-pox*, although they might have been infected if they had been exposed

to the more concentrated sources of infection. Nor can successful revaccination, nor its failure, be viewed as absolutely indicating a state of constitution which shall resist the infection of small-pox on all occasions, more especially when this malady is present in an epidemic form, although it may resist this infection on nearly all occasions, or with very few exceptions; these exceptions, however, being a mild or modified small-pox, in the great majority of instances.

1. VAGINA AND VULVA—DISEASES OF THE.—Affections of the vagina and vulva are as frequently surgical as strictly medical. As, however, certain of them require internal or constitutional means, either altogether or chiefly, in their treatment, they may be viewed as belonging to the latter category, although I can see no just reason for separating the two departments of practice, or for assigning them more to the one than to the other.

2. I. The VAGINA is liable to several congenital alterations, or vices of conformation. The chief of these are: 1st. Its opening in an abnormal situation; 2d. Its separation by a partition into two canals; 3d. Its imperforation; 4th. Its constriction; and, 5th. Its entire absence. As to either of these, I can add nothing to what will be

found in the many excellent recent works on surgical pathology. The last of these conditions is of great importance as respects the diagnosis, and the results proceeding from it. It may become the subject of medical investigation as respects especially the retention of the catamenia, and the propriety of an operation, on this account, after due deliberation. The absence of the vagina may be only partial; but even in this case, and when the exact state is ascertained, the question as to the propriety of attempting an operation for the establishment of the canal should not be entertained, unless there be a pressing occasion for having recourse to it, as it may compromise the life of the patient. But what occasions may suggest recourse to a surgical operation in such cases? These are: 1st Excessive uterine distention from an accumulation of the menstrual fluid; 2d. The supervention of metritis, or peritonitis, or both; and, 3d. Contamination of the circulation from the absorption of a portion of the retained and altered blood from the uterus. This operation has been, therefore, performed successfully by CABARET, VENTURA, DESGRANGES, DELPECH, WILLAUME, JEFFERSON, and COSTE; but unsuccessfully by LANGENBECK, MACFARLANE, and FRETAC (VELPEAU, *Médecine Opératoire*, t. iv., p. 356). The accumulated menstrual fluid may be discharged, in the urgent circumstances just stated, by puncture either by the rectum or by the bladder.

3 The diseases and organic lesions to which the VAGINA is liable, are *inflammations, ulcers, constrictions, or contractions and obliteration, tumours of various kind, polypi, fistulae, cancer, prolapsus, wounds, laceration, herniæ, and the impaction of foreign bodies*. Several of these belong more to the province of the surgeon than to the physician, or rather require surgical, in addition to medical means.

4. i. INFLAMMATION OF THE VAGINA.—SYNON. —*Vaginitis, Vaginite*, Fr

CLASSIF. —III. CLASS, V. ORDER (*Author in Preface*)

5. DEFINIT. —*Heat, soreness, or pain, in the course of the vagina, sometimes attended by increase of pain, or by uneasiness upon sitting down on a hard seat; and always by pain and tenderness on vaginal examination, and by a whitish or a muco-purulent discharge, with slight febrile disturbance, increased or returning at night.*

6. Inflammations of the vagina rarely occur, unless in connexion with inflammation of the vulva, or with inflammation of the neck of the uterus; most commonly with both, unless it be caused by violence, by excessive sexual indulgence, by irritating injections, and by foreign bodies, as pessaries, &c., lodged in the vagina. It commonly presents an *acute or sub-acute form*, whether simple or thus complicated; but it is also often *chronic*, especially when it is associated with disease of the neck or body of the uterus, and in many cases which are commonly viewed as simply those of leucorrhœa. In these *chronic and sub-acute* cases the mucous follicles of the vagina, and often also of the cervix and vulva, are more or less implicated—either partially or chiefly

7. A. *Acute vaginitis* rarely occurs in a simple or *sthenic form*, unless when it is *specific*, or *gonorrhœal*. In rare cases, also, it is *asthenic or diffusæ*, owing to the occasions about to be mentioned. *Acute sthenic vaginitis*, and the sub-

*acute states*, are most frequently consequences of the causes just stated, or of sitting on cold or damp seats, especially during, or soon after, the menstrual period. In these circumstances, it has been termed, by some physicians, *raginal catarrh*, or catarrhal inflammation of the vagina, especially in its slighter or sub-acute state. In this state, it is not unfrequently met with in pregnancy, and, in rare instances, as a complication of hæmorrhoids. In these simpler forms, vaginitis is attended by a copious whitish, or grayish, or nearly colourless mucous discharge, which soon passes into a muco-purulent and yellowish matter, especially when retained for some time in the vagina; there are also soreness and tenderness in the course of the vagina, sometimes with frequent micturition and slight dysuria. I have met with several cases, in public and private practice, of this form of vaginitis, as a sequela of measles, but much more frequently of scarlet fever, especially in children among the lower classes.

8. B. *Acute and sub-acute vaginitis* is often mistaken for *gonorrhœal vaginitis*, or the *blennorrhagia* of French pathologists, especially of M. RICORD and his disciples; and it is generally very difficult to distinguish between the simple and specific forms of the disease. Generally, however, the latter, or gonorrhœal, is attended by characteristic signs referable to the vulva; by itching, smarting, or stinging in this situation; by frequent painful micturition, by inflammation and swelling of the labia nymphæ and urethra; pain and soreness being greatly increased when sitting. The local signs and febrile symptoms are more acute, and the swelling, tenderness, and intolerance of an examination are greater, than in the non-specific states of vaginitis, and the discharge more copious and more completely purulent. In all the cases of gonorrhœal vaginitis which I have seen the disease extended to the uterus, and in three to the ovaria. In this form of the disease, the history of the case, especially with reference to the affection of the vulva, and the probability of its being caused by an impure connexion, will much assist the diagnosis. In most of the cases which I have seen, the disease was communicated by the husbands of the females affected, the fact of this having been the cause having been acknowledged by the former. In some instances, much difficulty has occurred in the diagnosis, especially when vaginitis has been produced soon after marriage, in consequence of excessive sexual indulgence, and of the states of both the male and female organs previously, and even of the constitution and habit of body of the female. A similar difficulty is sometimes met with in the vaginitis, follicular or mucous, which occasionally appears during pregnancy. In both these circumstances, the discharge may infect the husband, in such a manner as to be distinguished with great difficulty, or not at all, from gonorrhœa in the male. The *urethritis* thus produced on rare occasions is somewhat different from the specific disease, as far as my observation of a few cases enables me to state. The earlier signs referable to the opening of the urethra, and the distressing chordee characterizing, are either wanting, or are slight in the simple urethritis; while micturition is neither so painful nor so difficult as in the specific disease. The inflammation, however, of the former is more disposed to extend to the mucous surface of the

urinary bladder, and less disposed to affect the testicles, than that of the latter malady.

9. *C. Asthenic vaginitis*, or diffusive inflammation of the vagina, has been hitherto unrecognized. I have referred to two instances of its occurrence associated with adynamic dysentery in married females, when treating of *metritis* (see art. UTERUS, § 54), the inflammation having extended from the vulva to the vagina and uterus; and having been produced by the septic and infectious exhalations evolved, during a long continuance of warm weather, from full, open privies. In these cases the vaginal discharge was muco-purulent, streaked and discoloured with blood, and rusty, at times of a brownish, or greenish brown hue, and very abundant, with remarkable swelling and tenderness of the parts, and with the symptoms accompanying acute metritis (see UTERUS, § 55, *et seq.*). The pulse was rapid, weak, small, and compressible; the vital prostration and the other symptoms of adynamia being so marked as to require powerful tonics and restoratives. Recovery ultimately took place, but after a very protracted illness. This form of vaginitis may be complicated with asthenic dysentery, as observed in the cases now referred to.

10. *D. Phlegmonous inflammation* may attack the connecting cellular tissue of the vagina, especially that between the vagina and rectum, and occasion a small abscess, which may open either into the vagina or into the rectum. Inflammation also of some portion of the pelvic cellular tissue, or of the cellular tissue connecting the uterine appendages (see UTERUS, § 122, *et seq.*), may extend in this direction, and open into the vagina, occasioning more or less inflammation of this part or of the rectum, or even a fistulous communication between the vagina and rectum. When the inflammatory action is limited to the cellular tissue of the vagina and its immediate vicinity, and occasions only a small abscess between the vagina and rectum, the opening into either part is generally followed by quick recovery, unless the constitution be in fault, and then ulceration, or a fistulous communication between the vagina and rectum, may result.

11. *E. Consequences of Vaginitis.*—*a. Contraction and obliteration* of the vaginal canal is seldom observed, the latter especially. Either of these lesions may, however, occur after inflammations caused by injuries, wounds, lacerations, ulcerations produced by pessaries, foreign bodies, and irritating injections; but contractions in various grades and extent are much more frequent than obliteration, which is a very rare occurrence. Injuries or lacerations during delivery are the most frequent causes of these lesions. The injection of irritants and stimulants to provoke abortion has in a very few instances been recorded as a cause of both contraction and obliteration of the vaginal canal. These changes may occur in any part of the canal, but most frequently in the part next to the vulva, unless when they are caused by malignant disease, and then they generally commence in the cervix uteri, and extend to the portion of the vagina adjoining, and progressively to more or less of this canal. In the article UTERUS (§ 205) I have mentioned a case where nearly the whole of the vagina was obliterated by cicatrization consequent upon a rare instance of the spontaneous cure of malignant disease of the cervix uteri and vagina. Similar occurrences have been noticed by ROKITSKY.

12. *b. Chronic inflammation*, limited or more or less extended, sometimes either follows the acute and subacute states of vaginitis, or occurs primarily, but much more frequently as a consequence of the irritation caused by morbid secretions from the cervix uteri, or from the internal surface of the cervix or body of the uterus, and it is often complicated with inflammation of the cervix. This form of the disease may occur either in the puerperal or in the non-puerperal states, and it may, moreover, be complicated with, and then be masked by, the uterine disease, or by inflammation of the vulva, or by the leucorrhœal discharge, with which it is attended, both in its simple and complicated forms. Chronic inflammatory irritation, thus originating and related, may be followed by organic changes of an important nature, especially when it more particularly affects the mucous follicles, or extends to the connecting cellular tissue. In such cases *ulcerations*, and even *perforations*, of the vagina are not very rare occurrences. The ulceration may be *common*, *scrofulous*, *syphilitic*, or *cancerous*. The first of these usually occurs in consequence of inflammation, chiefly of the phlegmonous character noticed above (§ 10, *et seq.*), and commences either in the mucous follicles or in the connecting cellular tissue. In these follicles scrofulous ulcerations may also commence, or be chiefly seated. These latter have been well described by Dr CARSWELL; and Dr. HOOPER states that these ulcerations assume the character of scrofula in other parts. "The sides of the ulcerations are tumid; solid puriform depositions are found about them in the cellular structure between the membranes; and there are perhaps fistulous communications with the urinary bladder, rectum, or psoas muscle." Common and scrofulous ulceration may be developed either primarily or consecutively in the lacunæ and glandular bodies with which the lower part of the vagina is so abundantly supplied. When these glands are primarily affected, there is generally an abundant milk or cream-like discharge from the vagina, constituting a form of leucorrhœa, and depending upon chronic irritation or inflammation of them. This state of morbid action when prolonged, especially in cachectic or scrofulous constitutions, may go on to ulceration, or even to fistulous perforations. Disease of these glands, and chronic inflammation of the vaginal surface, may also be developed or perpetuated by the morbid secretions from an inflamed or otherwise diseased cervix uteri, or internal surface of the uterus, or of its cervix. The most extensive ulcerations and perforations with fistulous communications with adjoining parts are produced by pessaries or other foreign bodies lodged in the vagina. SYPHILITIC and CANCEROUS ulceration of the vagina are noticed in the articles on Cancer of the UTERUS and on VENEREAL DISEASES.

13. *Complications of Vaginitis.*—Acute or chronic vaginitis may be associated with inflammation of the cervix uteri, or with vulvitis, or nrethritis, or even with two or all of these. It is chiefly in girls under twenty that the complication with vulvitis is observed. In some instances of this complication an abscess forms in the labia majora, especially when inflammation of the vagina and vulva is severe; and when the inflammation extends to the subjacent cellular tissue of cachectic habits, phagedæna of the parts may supervene. Gonorrhœal vaginitis is generally associated with urethritis and vulvitis, and often also

with sympathetic bubo, this latter being the consequence of inflammation of the lymphatic vessels and glands. Vaginitis is, in some cases, complicated with endo-metritis, and more rarely also with inflammation of the uterine appendages, especially when it is of a specific kind, as noticed above (§ 8, 9). In this complication the inflammation may originate either in the uterus or in the vagina, and extend to the other parts. Vaginitis may also occur during pregnancy, and disappear after parturition.

14. ii. TREATMENT.—The treatment of the non-specific or common states of inflammation of the vagina is generally simple, and is locally and constitutionally antiphlogistic. In severe attacks, leeches should be applied to the upper parts of the insides of the thighs, or to the groins or perineum, and the bleeding be promoted by warm fomentations, &c. Tepid or warm baths, general or local; cold, tepid, or warm injections into the vagina; cooling aperients, and cooling diaphoretics, and an antiphlogistic regimen, are the chief means of treatment, especially in the more acute cases, and in the early stage. Aperients which irritate or excite the large bowels should be avoided; and those injections, alvine and vaginal, which produce a cooling and an emollient effect, not only on the large bowels, but also on the vagina, should be selected. The injection of cold or tepid water into the vagina washes away the morbid secretion, which by remaining even for a short time, and accumulating in this part, increases or perpetuates the inflammatory irritation. Several medicated injections, either emollient, astringent, or anodyne, may also be prescribed. When the irritation, tenderness, or pain, is considerable, milk-and-water, linseed tea, decoction of marsh-mallows, either tepid or cold, may be administered, with a little sirup of poppies, and with either a small quantity of the nitrate of potash or of the biborate of soda. If the inflammation be severe, the emollient injections may contain either these in somewhat larger quantity, or a small quantity of the hydro-chlorate of ammonia. Or instead of those the decoction of poppy-heads may be employed, with the saline substances just mentioned, or simple water with the acetate of lead and a few drops of laudanum.

15. When the more acute and severe symptoms have subsided, then the more energetic astringents may be prescribed, such as the sulphate of alumina, the sulphate of zinc, acetate of lead, solution of the nitrate of silver, decoction of oak-bark, and solution of tannin. Dr. H. BENNET states that the first three he generally uses in the proportion of a drachm to a pint of water, increasing or diminishing the strength according to circumstances; and after much experience he concludes that alum is the most efficacious of all these agents, with the exception of nitrate of silver. In order that injections may be efficacious, they should be administered abundantly, frequently, and with such appliances as may allow them to remain for some time in the vagina.

16. For *gonorrhœal vaginitis*, the antiphlogistic treatment advised for the early stage of common or simple vaginitis should be energetically prescribed, and cooling diaphoretics and aperients, with demulcents, emollients, and diluents, freely used. The irritation of the urinary bladder and urethra, and the associated vulvitis, will be most surely allayed by these means, aided by fomentations, warm local and general baths, and by the

emollient and anodyne injections advised above (§ 14). The patient should partake freely of mucilaginous diluents containing the nitrate of potash or of soda, and the carbonates of the fixed alkalies, with very small doses of camphor. After the acute symptoms have been subdued, the more astringent injections mentioned above may be resorted to. If gonorrhœal rheumatism should occur, which is seldom observed in females, the treatment for that species of rheumatism, advised in the article RHEUMATISM (§ 163), should be directed. Gonorrhœal vaginitis extending to the cervix uteri, or occasioning endo-metritis, requires the means advised for this complication in the article UTERUS (§ 124).

17. *Asthene vaginitis*, in the form which I noticed above, as having fallen under my observation, requires a frequent recourse to vaginal injections. Those which I prescribed consisted of alum, or of sulphate of zinc, with a little camphor and laudanum; the decoction of cinchona, with the compound tincture of cinchona, nitrate of potash, and bicarbonate of potash, being taken internally; and full doses of DOVER'S powder at night; lime-water, or potash-water, with milk, being the beverage generally allowed.

18. As regards *other lesions* implicating the vagina, especially *ulcers, fistula, lacerations*, or extensive *ruptures, wounds, hernia, polypi, tumours* of various kinds, *foreign bodies* lodged in the vagina, *prolapsus* of the vagina, and *cancer* of the vagina (see art. UTERUS, § 190 *et seq.*). I must refer the reader to surgical works, or to the article VAGINA, by MM. DESORMEAUX and P. DUBOIS, in the second edition of the *Dictionnaire de Médecine*, where these lesions are very ably described.

19. II. THE VULVA is liable to diseases which are either local or constitutional. The latter requires internal or constitutional treatment chiefly, and sometimes local means also; the former seldom receives permanent benefit from local appliances, without having recourse at the same time to general or internal medication. The affections of this part, as well as of several others, show that no distinction should be made respecting those which are commonly called medical and those which are usually termed surgical; although I am obliged, by the scope and limits of this work, to observe this distinction to a considerable extent. Diseases of the vulva are of frequent occurrence at all ages, and in all classes of society. They often assume serious characters, owing to concealment, neglect, or delicacy of feeling, more especially in childhood, or in early or mature age. They most frequently proceed from want of due cleanliness, from infection, from eruptive and other fevers, from diseases of the uterus and appendages, and from masturbation. The puerperal states have also some influence in causing them. They may occur primarily or consecutively; and in either case they may be simple, or complicated with whatever disorder they may induce, or be induced by.

20. i. INFLAMMATIONS OF THE VULVA.—*Vulvitis*. CLASSIF.—III. CLASS, V. ORDER. (*Author.*)

21. DEFINIT.—*Pain, soreness, and tenderness of the vulva, frequently with swelling, painful micturition, and more or less symptomatic fever.*

22. *Vulvitis* may assume every grade of severity, from the slightest pruritus and inflammatory irritation, to erythema, to phlegmonous, diffusive erysipelatous, and to ulcerative or gangrenous in-

inflammations, simple, or complicated. I shall briefly notice these, as well as other forms of disease of the vulva which fall under the category of inflammatory, either sthenic or asthenic, and offer some remarks on these varieties of vulvitis which have fallen under my observation at the Infirmary for Children and in private practice, and commence with the slightest or least inflammatory in appearance, and proceed to the more violent and dangerous.

23. *A. CATARRHAL VULVITIS.*—This form of the disease is usually slight, unless it be neglected or aggravated by neglect of cleanliness. It is not unfrequent in children; and in grown-up females it occurs as a form of leucorrhœa, or as a symptom of disease of the neck or body of the uterus. In infants and children especially, it assumes a catarrhal appearance, the discharge being at first chiefly mucous, and afterward muco-purulent; the surface of the vulva being slightly red and swollen; but neither very irritable nor excoriated, unless neglected. It is most frequently caused by cold, by sitting on cold or damp seats, by general debility, and the irritation of ascarides in the rectum, or by disorder of the digestive organs. It is sometimes a sequela of low and eruptive fevers in childhood, especially of scarlet fever; and if it be overlooked, or continue long, it may give rise, especially if aggravated by filth and an improper regimen, to one or other of the more serious forms of vulvitis about to be described.

24. *B. IRRITABLE VULVITIS.*—As observed in some states of the disease of the uterus, so in some affections of the vulva, the inflammatory appearances are either slight or not very remarkable; yet the pain and tenderness are very great, or even acute. Sensibility is so morbid as not to admit of the slightest touch; and in married females sexual intercourse cannot be endured. On examination, the parts are slightly red, or rose-colored, and covered in parts by a whitish exudation, especially about the entrance of the vagina; in some cases there is also slight swelling or fullness of the labia. The patient complains of a sense of heat, or lancinating pains of the parts, of smarting, painful micturition, and of inability of walking. This complaint is sometimes caused by the state of the menstrual discharge, and is most frequently met with in young persons about the age of puberty, or shortly before or after the first appearance of the catamenia, in females after marriage and during their first pregnancy, and in widows, but less frequently in these last. It is sometimes associated with one or other of the forms of hysteria, or with spinal irritation.

25. *C. PRURIGINOUS VULVITIS.*—*Pruritus* of the vulva is often a very distressing disorder. The itching or pruritus of the parts is sometimes such as cannot be endured without resorting to friction in some way or other to allay it. There is generally a sense of heat, but seldom much pain, tenderness, or soreness of the parts, unless what may be caused by the frictions resorted to. Nor is there much redness or swelling, unless such as may be referred to the same cause. But there is obviously more or less vascular erythsm of the parts, or of others in their vicinity, sometimes with increased secretion from the surface or interior of the labia and orifice of the vagina, or even a more copious discharge, owing to the frictions resorted to. This disorder is not unfrequent previously to or after puberty, and often is attended by inordinate sexual desire, amounting in some instances to

nymphomania, and frequently suggesting masturbation, which, although it may assuage the irritation for a time, generally tends to perpetuate or aggravate the disorder. *Pruritus vulvæ* is also a frequent consequence of pregnancy, especially of the first pregnancy, in young plethoric habits and sanguineous temperaments, of the discharges after parturition, and of morbid states of the catamenia. In both girls and married females it is often caused by the state of the secretions from the follicles of the vulva and vagina, especially when they are allowed to accumulate and irritate, owing to their alteration by the oxygen of the atmosphere, the sensitive mucous and erectile tissues of these parts. It is also at all ages sometimes symptomatic of worms, especially of ascarides in the rectum.

26. *D. ECZEMATOUS VULVITIS.*—An eruption of an eczematous character (see *art* ECZEMA, § 9) is sometimes met with on the internal or external surface of the labia vulvæ, and is either dry or humid, and occasionally extends to the adjoining parts of the thighs. It generally presents a copper-coloured redness, is liable to recur at intervals, and often continues for an indefinitely prolonged time. It is attended by a sense of heat or burning, with a stinging itching. It seldom occurs in young females, but is very common after 35 or 40 years of age, and especially after the cessation of the catamenia; and in those it may continue for years, particularly in females of a full habit of body, or who are corpulent. It is not necessarily connected with any venereal infection or with leucorrhœa, although this latter may be associated with it.

27. *E. ERYTHEMATOUS VULVITIS.*—The internal surfaces of the labia are not unfrequently slightly swollen, diffusely red, painful and smarting, and intolerant of touch. It presents no appearance of phlyctena, is smooth or shining, the surface being hot, with a sense of more or less of painful heat. It soon becomes covered by an exudation of a whitish or ichorous lymph; and in some cases which I have seen at the Infirmary for Children, the labia have become adherent, and so firmly adherent as to require surgical aid in separating them. This form of vulvitis is not uncommon in children of all ages, especially in those of a very full habit of body, and in these, as well as in corpulent females advanced in life, is owing to the acrimony of the secretions from the parts in their vicinity, to the state of the menstrual discharge, or of the lochia, and to the neglect of cleanliness. In many cases the discharges from the vagina, and cervix and os uteri, occasion or perpetuate the inflammation of the vulva. Although a comparatively slight disease, the neglect of it may be followed by more serious results; such as phlegmonous or suppurative inflammation, by inflammation of the lymphatics, or even, in rare instances, in young children, by adhesions of the labia.

28. *F. ERYSIPELATOUS VULVITIS.*—This form of vulvitis generally resembles the erythematous at its commencement; but owing to the state of the secretions producing it, or the habit of body of the patient, or to both, it is soon characterized by great swelling, and a disposition to terminate in suppuration, or sphacelation of the more superficial parts. It is attended by a quick pulse, and by more or less severe constitutional disturbance. This often becomes a serious disease, and goes on to diffuse phlegmon, or phlegmonous erysipelas. In the most unfavourable cases, particularly in

cachectic habits, it is liable to occasion gangrene of the integuments, extending even to the adjoining parts. It results most frequently from the same causes as the foregoing varieties of vulvitis acting on cachectic habits of body, and during morbid conditions of the circulating fluids.

29. *G. PELLICULAR VULVITIS*.—Since M. BRETONNEAU described inflammation of mucous surfaces with the exudation of lymph—forming a false membrane over the inflamed surface—a form of disease which he termed *diphtheritis*—inflammation of the vulva with the formation of a false membrane—*Vulvitis diphtherique*, of French pathologists, has been occasionally observed in circumstances similar to those which occasion this form of inflammation in the cavities of the mouth, pharynx, &c., or when this disease of the mucous surfaces is endemic or epidemic. This form of vulvitis differs from all others in the rapid formation of a false membrane on the inflamed, but very slightly swollen, surface. As it is observed in the mouth and pharynx, so it is found to extend to the adjoining canals, advancing up the vagina to the neck of the uterus, or into the urethra. This state of the disease is obviously the result of constitutional disorder, in which the circulating fluids are in some degree, although not always demonstratively, affected. It is most frequently observed in girls or young females, at certain seasons or localities of a cold and humid description; and the febrile disturbance attending it presents an asthenic, rather than a sthenic character.

30. *H. PILEGMONOUS VULVITIS*.—Inflammation of a phlegmonous form may commence either in the cellular tissue beneath or connecting the mucous and cutaneous structures, or in the more deep-seated mucous follicles of the vulva, or at the commencement of the vagina. It has been assigned to one or other of these seats exclusively by various pathologists; and it may very possibly originate in either, although most probably in the mucous follicles, in consequence of obstruction in their ducts. This affection generally appears with heat and tension of the parts, followed by a dull and sometimes a severe pain, and affects chiefly, or more frequently, the lower halves of the substance of the labia majora. Pain, and a sense of weight, tension, and fulness, extend to the perinæum, and more or less febrile disturbance is developed, which may, in the course of two or three days, assume a severe inflammatory character. The bowels are confined, and the urine scanty, high-coloured, and passed with pain. The whole vulva becomes hot, and one or other of the labia is thickened and swollen, the inflammation and tumefaction extending near to the perinæum. In the course of five, six, or seven days, an abscess commences in the centre of the inflamed tissues; and although it cannot be perceived externally, it may be felt by firmly grasping between the fingers of one hand the swollen labium. A tumour the size of an egg, or smaller, will then be found in the midst of the tumid structure; and if the abscess be at all advanced, fluctuation will be perceived by a finger of the other hand.

31. *Abscess of the vulva* occurs only on one side at the same time, and very rarely attacks both in succession. It is observed chiefly in young females, and especially in the recently married, and very rarely at a greater age than 40 years. M. VELPEAU met with a case in a female aged 44. I was consulted in a case of a lady who admitted

her age to be 45. This distinguished physician states that it is commonly a result of excessive coition, of disproportion between the sexual organs, or of the introduction of a foreign body into the vagina; that it may also arise from neglect of cleanliness, from irritation of any kind, whether externally and mechanically, or internally and pathologically; and that in 18 cases out of 20 it occurs in girls who have prematurely had sexual intercourse, in prostitutes, and in young females who have indulged in excessive venereal pleasures or in masturbation. It is sometimes a consequence of leucorrhœa and of gonorrhœa, and of any violence or irritation to which the vulva has been subjected.

32. The *course* of abscess of the vulva is generally rapid, but owing to the structure of the parts, and to the circumstance of females being aware of the cause of the complaint, medical advice is deferred as long as possible; and the history of the early symptoms and changes is not obtained until the abscess has either burst or is ripe for opening. When left to itself, it generally bursts from the seventh to the twelfth or thirteenth day; when it has acquired a size varying from that of a nut to that of a hen's egg. It rarely exceeds this latter size. Phlegmonous vulvitis very rarely *terminates* in resolution, and seldom in sphacelation or gangrene, and then only in cachectic habits of body. When abscess of the vulva opens spontaneously, it is generally by a perforation in the direction of the vaginal surface of the labium. In some instances more than one perforation is observed when the abscess has been large. A fistulous communication may even form, and, in rare cases, extend to the rectum, or by the side of the vagina to or around the urethra. In most cases, however, the abscess is discharged and healed in the course of a week or two. But if sexual intercourse take place during this period, the abscess may be reproduced, owing to the injury or irritation of the cicatrix, and of the tender parietes of the former abscess, and to the greater susceptibility of the parts. Hence abscess of the vulva may be reproduced several times in the same female. M. VELPEAU has seen it thus recur six, eight, or ten times in the course of a few years.

33. *I. ULCERATIVE OR ASTHENIC VULVITIS*.—*Noma, Phagedænic ulceration of the labia vulvæ, Gangrene of the vulva, Gangrenous inflammation of the vulva.* VELPEAU.—This form of vulvitis is observed chiefly in children from about the period of weaning to the ninth or tenth year of age. It was first described by Mr. KINDER WOOD, and occurs chiefly in ill or insufficiently fed children, in those who live in low, unhealthy, or crowded localities or apartments; or who are the subjects of low, adynamic, or gastric forms of fever; and in delicate, cachectic, and anæmic habits of body, especially in large manufacturing or other cities and towns. The disease may be preceded, as well as attended, by loss of appetite, nausea, thirst, and other febrile symptoms of an adynamic character. The pulse is quick, small, or weak; the countenance and general surface pale or sallow, and the tongue is pale and covered by a dirty-looking or clayey coating or fur. The patient first complains, locally, of painful or scalding micturition, or cries or struggles violently when voiding the urine. The labia vulvæ are inflamed and enlarged, and their surfaces are of a purple or livid-red tint, the inflammation extending over the clitoris, nymphæ,

and hymen, and even into the urethra. A thin exudation may at this early period be observed covering these parts, which may proceed from the irritation having extended to the lower part of the vagina. Twenty-four hours hardly elapse until a number of small vesications appear within the labia, as well as externally, and soon afterward burst, quickly spread into each other, and form large ulcers. In other cases the inflamed surface passes into the ulcerated state without any manifest vesication. The thin exudation mixes with the secretion from the ulcerations; the resulting discharge is dark-coloured, sanious or ichorous, copious, very offensive, and irritating to the tissues, and rapidly extends the disease to the perinæum and anus, and to the thighs contiguous to the labia.

34. The constitutional symptoms are now most seriously adynamic. The pulse is rapid, irritable, and compressible; the face and general surface are white or blanched; the bowels torpid, and the stools offensive. The patient lies constantly on her back, with the knees bent and wide apart; and the distressing pain caused by micturition prevents her from using any effort to void the urine. The ulcerations vary in appearance and depth. In some cases they are foul and deep, in others they are superficial, and their bottoms present small red granulations; their states varying with the severity, constitutional tendency, and the treatment of individual cases.

35. The terminations of the disease also depend much upon the circumstances just now stated. When the ulceration is fully established, the swelling of the labia vulvæ diminishes, and the redness disappears with the extension of the ulceration, which is deep, foul, and spreading, in states of the system manifestly adynamic and cachectic, and of the circulation not only anæmic, but also contaminated. The secretion from the ulcerated surface extinguishes the vitality in succession of the tissues with which it is in contact, until the external organs are progressively destroyed. As the process of destruction advances, the face becomes more blanched, the pulse remarkably rapid and small, the appetite lost, the bowels loose, the stools offensive; emaciation and anæmia being remarkable, and the discharge from the ulcerated surface most offensive; and the patient expires in the course of a few days, the duration of the disease varying much with the circumstances and treatment of individual cases.

36. If, however, this affection be seen early, and be judiciously treated, the ulcerations become clean and heal. Yet, after they heal, a yellowish discharge often continues for a considerable time from the vagina and affected parts; and causes, where due precautions are neglected, a recurrence of the malady. In most cases, owing chiefly to the extent of the constitutional disturbance—to the low grade of vitality, and to the contamination and insufficiency of the blood—the recovery of the patient is generally protracted, and is rarely of less duration than eight or nine weeks. When the ulceration is large and deep, the patient very rarely recovers, although the most decided means to arrest its progress be employed.

37. The nature and morbid relations of this most dangerous form of vulvitis are manifest from the above. It has been viewed by M. VELPEAU as a gangrenous inflammation of the vulva; but the destruction of tissues quickly following

the vesications on the inflamed, swollen, and livid parts is not altogether similar to true gangrene, but rather to that of phagedænic or rapidly destructive ulceration. It resembles in most respects *cancrum oris*, or that form of stomatitis which I have described by the name of *stomatitis phagedæmica* (see art. STOMATITIS, § 24, *et seq.*). The causes of both maladies are the same—they are both consequent, in rare instances, on low fevers, continued, remittent, and exanthematous, more especially on scarlet fever—and they are both arrested when admitting of this termination by the same or similar means.

38. K. GONORRHOICAL VULVITIS.—*Specific Vulvitis*.—This form of the disease, if not always, is generally attended by more or less irritation of the urethra. The following is nearly the description of the disease by M. RICORD, as quoted in Mr. ACTON'S able work. This complaint may affect the epithelium of the mucous surface only, or the vulvar glands also, these glands, according to M. MOULINIER, being regarded as the organ secreting the venereal virus. At first the patient complains of an unusual sensation in the vulva, with a desire for sexual intercourse. This is soon followed by itching, heat, redness, and swelling. The normal moisture of the parts is much augmented; but it soon becomes increased and irritating, and aggravates the inflammation. The discharge rapidly assumes a muco-purulent state, owing to the affection of the mucous follicles. As the inflammation extends more deeply, the swelling increases; and it may then become phlegmonous (§ 30, *et seq.*), or be attended by œdema. If the nymphæ become inflamed, they may be so enlarged as to protrude beyond the labia. Abscess may follow the swelling, or the inflammation may extend to the vulvar glands, and occasion small abscesses. Owing to the extension of the morbid action to the urethra, and to the state of parts now described, the urine is voided frequently, and produces much scalding and smarting. Patients who have been subject to leucorrhœa readily distinguish the difference between the discharge and other symptoms now experienced, and those to which they have been subject. With very exaggerated sensibility of the vulva, the scalding on passing urine becomes very severe, and in some cases retention of urine occurs. The inflammation may even extend along the urethra to the neck of the bladder, producing very painful and constant desire of micturition. The existence of urethritis in these cases may be ascertained, if the patient has not recently passed water, by introducing the finger into the vagina, and then pressing the urethra from behind forward; if muco-pus be in the urethra, it will be at once evident. *Syphilitic ulceration* of the vulva is noticed under the head of VENEREAL DISEASES.

39. L. CONSEQUENCES OF VULVITIS.—These are, as partially noticed above, œdema, abscess, ulceration, and molecular gangrene, sphacelation, extension of the inflammation to the vagina and cervix uteri, or to the urethra and neck of the bladder, or to the lymphatics and lymphatic glands. Œdema vulvæ, although sometimes caused by inflammation, is more frequently a consequence of organic disease of the heart, or of the kidneys, or of other internal organs; and it is thus generally associated with anasarca. It may also occur during the advanced stage of pregnancy, or even after parturition; in the former circumstances

often rendering delivery more serious or complicated, and in the latter increasing the amount of suffering, and delaying recovery. Inflammation of the lymphatics and their glands rarely occurs in the course of vulvitis, but chiefly of the phlegmonous, ulcerative, and specific forms. It is seldom detected until pain and swelling are experienced in the inguinal glands, and then irregular streaks of redness may be perceived in the external parts, with irregular hardness or swelling of the labia, extending superficially to the groins.

40. ii. TREATMENT.—*A. The treatment of catarrhal vulvitis* (§ 23) consists chiefly of frequent ablutions with weak solutions of alum or sulphate of zinc, or with camphor-water, or seawater, &c. If the parts present much inflammatory irritation, the local means advised for the *irritable* and *erythematous* states of the complaint may be directed, and the treatment be in other respects the same. In most cases, and especially when connected with debility, or occurring as a sequela of fevers, &c., then warm salt-water bathing, followed by tepid or cold salt-water bathing, or warm salt-water hip-baths; tonics internally, chalybeates, due attention to the digestive, assimilating, and excreting functions, and change of air, &c., will be found of very great service.

41. *B. Irritable vulvitis* (§ 24), *Pruriginous vulvitis* (§ 25), and *Erythematous vulvitis* (§ 27), are so closely allied states of inflammation, and so generally affect only or chiefly the epithelial mucous surface, as to require the same or very similar means of cure. At first emollient or demulcent lotions, containing a sedative or narcotic tincture, or solution, in small quantities; or weak solutions of the acetates of lead, or of the nitrate of potash, or hydrochlorate of ammonia, in the decoction of poppies; or a saturated solution of the bichlorate of potash, in camphor-water, or in the decoction of marsh-mallows; or cooling pomades, as cold cream, &c., may be prescribed. In the more obstinate or severe cases, pomades containing the oxyde of zinc, or the chloride of mercury, &c.; or lotions with a small quantity of the nitrate of silver, or bichloride of mercury, or of the sulphate of zinc. Or demulcent applications, containing camphor, with one or other of the substances just mentioned, may be resorted to. As these several forms of vulvitis are often symptomatic of disease of some adjoining organ, more especially of inflammatory irritation of the neck of the uterus, of leucorrhœa, of the irritation of worms in the rectum, of gravel or calculi in the bladder, &c., these morbid relations of the forms of vulvitis now being considered should not be overlooked; and the treatment ought to be directed more especially to the cure of the complaint of which they are severally a symptom merely, but a symptom which also requires removal.

42. *C. Eczematous vulvitis*, or eczema of the vulva, may be treated by similar means to those now recommended, or by the local and constitutional remedies mentioned in the article ECZEMA (see § 16, *et seq.*).

43. *D. Erysipelatous vulvitis* is often a serious disease (§ 20), and arises from the same, or nearly the same, causes as those producing the erythematous variety. In most of the cases of the former, however, the constitution is more in fault, especially the circulating fluids, than in the latter. The treatment, therefore, of this form should be more energetic, and be directed chiefly with the objects of depurating the blood, and support-

ing vital power and resistance. The former intention will be fulfilled by the exhibition of a smart emetic at an early stage, followed by a mercurial purge, and by saline aperients and depurants. After the prima via has been sufficiently evacuated, tonics should be conjoined with the alkaline carbonates, and such local means resorted to as the state of the parts may suggest. If diffusive phlegmon, or abscess, or gangrene supervene, the constitutional treatment should be energetic, and the local measures the same as advised for the phlegmonous and phagedænic forms of the disease (§ 45, 46), especially scarifications and incisions, which, when practised before suppuration or sphacelation commences, often prevent those serious consequences of the malady.

44. *E. Pellicular vulvitis* is generally most successfully treated by applying to the affected surfaces powdered alum, or calomel, or borax, with mucilage or honey, or strong solutions of the nitrate of silver, or of the chlorides, &c. Having arrested this form of the disease by these means, emollient or detersive lotions, hip-baths, and the remedies advised for the milder varieties of vulvitis may then be prescribed (§ 40, 41). The constitutional treatment should depend upon the peculiarities and circumstances of the case. But generally this form of the disease is not benefited, but it may be injured, by vascular depletions; while saline aperients, and alkaline, saline, and other depurants of the blood, conjoined with tonics, are beneficial. The treatment of this variety of the disease is in most respects the same as I have advised for *pseudo-membranous STOMATITIS* (see § 14, 15).

45. *F. Phlegmonous vulvitis* (§ 30, *et seq.*) may, when left to itself, especially in cachectic habits of body, occasion serious destruction of parts, sinuses and fistulous openings and communications with adjoining organs, or prolonged ulcerations. To prevent these consequences: 1st. The patient should be kept in bed, or on a couch, in a cool temperature, with the thighs wide apart; 2d. A considerable number of leeches should be applied between the labium and thigh, or upon the perinæum; 3d. To cover the phlegmon, twice or thrice daily, with mercurial ointment previously to applying linseed poultices; 4th. To direct a warm bath every second day, or a hip-bath every evening or night (VELPEAU). The abscess may spontaneously open, when thus treated, from the fifth to the eighteenth day; but it is generally more beneficial to open the abscess as soon as matter is formed, than to wait for a spontaneous discharge, which may take place in an undesirable situation, or after the abscess has occasioned more or less serious alterations, such results being not uncommon in unhealthy constitutions. The question as to the situation in which artificial opening of abscess of the vulva should be made has been decided by M. VELPEAU in favour of the external surface of the affected labium, and in the lower or posterior part of the swelling or abscess, for reasons he has assigned in the article referred to in the BIBLIOGRAPHY.

46. *G. Phagedænic ulceration of the vulva* (§ 33, *et seq.*) is the result of a molecular loss of vitality of the tissues poisoned by the contact of the irritating and contaminating fluid into which the dead molecules are resolved. It is identical in its nature with *phagedænic stomatitis*, as already stated; and the local as well as the constitutional treatment is in every respect the same as I have
